# CONTENTS OF SECTIONS

**PROCEEDINGS VOLUME 51, 1958**

| | PAGE Sect. | Vol. |
|---|---|---|
| **Book Reviews** | | |
| *January No.* | — | 39, 53 |
| *February No.* | — | 133 |
| *March No.* | — | 221 |
| *April No.* | — | 275 |
| *May No.* | — | 371 |
| *June No.* | — | 465 |
| *July No.* | — | 577 |
| *August No.* | — | 687 |
| *September No.* | — | 785 |
| *October No.* | — | 885 |
| *November No.* | — | 973 |
| *December No.* | — | 1061 |
| **Section of Anæsthetics** | | |
| *March No.* Meeting Jan. 3, 1958 | | |
| DISCUSSION ON ORGANIZATION FOR IMMEDIATE POST-OPERATIVE RECOVERY PERIOD | 1 | 151 |
| Dr. Russell M. Davies | 1 | 151 |
| Mr. J. R. Belcher | 3 | 153 |
| Dr. T. B. Boulton | 4 | 154 |
| Dr. A. C. Fraser, Dr. Eric Gardner, Dr. G. F. Rawdon Smith, Dr. J. Alfred Lee, Dr. Laurence Mountford | 5 | 155 |
| Mr. St. John Birt, Professor E. A. Pask, Mr. Belcher, Dr. Davies | 6 | 156 |
| *August No.* Meeting March 7, 1958 | | |
| DISCUSSION ON THE EXTRACORPOREAL CIRCULATION | 7 | 579 |
| Dr. H. C. Churchill-Davidson [*Abridged*] | 7 | 579 |
| Dr. Cyril F. Scurr | 9 | 581 |
| Dr. John Beard | 17 | 589 |
| Dr. W. A. Hudson | 19 | 591 |
| *October No.* Meeting April 11, 1958 | | |
| Meeting to Commemorate the Centenary of the Death of John Snow | | |
| JOHN SNOW'S LONDON ASSOCIATIONS. By George Edwards, L.R.C.P., M.R.C.S. | 21 | 831 |
| JOHN SNOW AND THE ENLIGHTENMENT. By M. H. Armstrong Davison, M.B.E., T.D., M.D. | 24 | 834 |
| **Clinical Section** | | |
| *March No.* Meeting Nov. 8, 1957 | | |
| GUMMATOUS ULCERS WITH GROSS HEPATOMEGALY AND ANÆMIA. By A. B. Wootliff, M.B., Ch.B. (for J. M. Milloy, F.R.C.S.) | 1 | 177 |
| ADDISON'S DISEASE WITH GLYCYRRHIZOPHILIA. By J. P. Knowles, M.B., B.Chir., D.Obst. (for Richard Asher, M.D., F.R.C.P.) | 2 | 178 |
| *March No.* Meeting Dec. 13, 1957 | | |
| PULSELESS DISEASE AND PULMONARY SARCOIDOSIS. By T. M. Chalmers, M.D. | 3 | 179 |
| TRAUMATIC ANEURYSM OF THE POPLITEAL ARTERY IN A BOY AGED 11 YEARS, ASSOCIATED WITH AN OSTEOMA OF THE LOWER FEMUR. TREATMENT BY ANEURYSMECTOMY AND REPAIR OF VESSEL WALL. By A. M. Desmond, F.R.C.S. | 3 | 179 |
| ECTOPIC PHÆOCHROMOCYTOMA. By R. E. Williams, M.R.C.P. (for Professor M. L. Rosenheim, C.B.E., F.R.C.P., B. J. Harries, F.R.C.S., and John Lister, M.D.) | 4 | 180 |
| POSTURAL APHONIA. By A. G. Grant, L.R.C.P.I., L.R.C.S.I. (for F. Boyes Korkis, F.R.C.S.) | 6 | 182 |
| *May No.* Meeting Feb. 14, 1958 | | |
| Meeting at the Middlesex Hospital, London | | |
| HYPOPHYSECTOMY FOR INCIPIENT BLINDNESS DUE TO PROGRESSIVE DIABETIC RETINOPATHY. By J. D. H. Slater, M.B., M.R.C.P. (for J. D. N. Nabarro, M.D., F.R.C.P.) | 7 | 365 |
| SENSORY NERVE CONDUCTION AFTER TRACTION LESION OF THE BRACHIAL PLEXUS. By George Bonney, M.S., F.R.C.S., and R. W. Gilliatt, D.M., M.R.C.P. | 7 | 365 |
| TRAUMATIC, RIGHT-SIDED, DIAPHRAGMATIC HERNIA: A MISTAKE IN DIAGNOSIS. By J. K. Ross, F.R.C.S., and L. P. Le Quesne, D.M., F.R.C.S. | 9 | 367 |
| RENAL TUBERCULOSIS. ILEOCYSTOPLASTY. By E. W. Riches, M.C., M.S., F.R.C.S. | 11 | 369 |
| *August No.* Meeting March 14, 1958 | | |
| CARCINOMA OF PANCREAS. By Paul T. Savage, M.B., F.R.C.S. | 13 | 593 |
| PHÆOCHROMOCYTOMA. By W. W. Davey, M.D., F.R.C.S., F.R.C.S.I. | 14 | 594 |
| TRACHEO-ŒSOPHAGEAL FISTULA WITHOUT ATRESIA. By R. H. Franklin, F.R.C.S. | 15 | 595 |
| *August No.* Meeting May 9, 1958 | | |
| Meeting at the Canadian Red Cross Memorial Hospital, Taplow, Maidenhead | | |
| THE EYE CHANGES OF STILL'S DISEASE: TWO CASES ILLUSTRATING TREATMENT. By W. K. Smiley, M.B., D.O.M.S., F.R.C.S. | 17 | 597 |

| | PAGE Sect. | Vol. |
|---|---|---|
| POLYARTERITIS NODOSA AND HYDRONEPHROSIS. By G. S. Wakefield, M.R.C.P. (for Professor E. G. L. Bywaters, F.R.C.P.), and Raymond Ramsay, M.B.E., F.R.C.S. .. | 18 | 598 |
| ENCEPHALOMYELITIS DUE TO VIRUS B. By Philip H. Willcox, M.D., M.R.C.P. .. .. .. .. | 20 | 600 |

**Section of Comparative Medicine**

*January No.* Meeting Oct. 16, 1957

| | | |
|---|---|---|
| COMPARATIVE ASPECTS IN VIROLOGY. President's Address by J. B. Brooksby, D.Sc., Ph.D., M.R.C.V.S. | 1 | 1 |

*May No.* Meeting Dec. 18, 1957

| | | |
|---|---|---|
| SYMPOSIUM ON RECENT DEVELOPMENTS IN IMMUNIZATION AGAINST BACTERIAL DISEASE .. .. .. | 9 | 375 |
| THE BASIS OF IMMUNITY TO ANTHRAX. By H. Smith, D.Sc., Ph.D., B.Sc... | 9 | 375 |
| STRAIN 19 AND OTHER BRUCELLA VACCINES. By E. C. Hulse, B.Sc., M.R.C.V.S. .. .. .. .. | 11 | 377 |
| IMMUNOLOGICAL RESPONSE TO FREEZE-DRIED BCG. By J. Ungar, M.D... | 14 | 380 |

*July No.* Meeting March 19, 1958

| | | |
|---|---|---|
| DISCUSSION ON COMPARISON OF DISORDERS OF THE INTERVERTEBRAL DISC IN MAN AND ANIMALS .. | 19 | 569 |
| Mr. D. D. Lawson.. .. .. | 19 | 569 |
| Dr. R. N. Smith .. .. .. | 21 | 571 |
| Mr. Arthur Naylor .. .. | 23 | 573 |

*September No.* Meeting Feb. 19, 1958

| | | |
|---|---|---|
| IRRADIATED HELMINTH LARVÆ IN VACCINATION. By W. F. H. Jarrett, Ph.D., M.R.C.V.S., F. W. Jennings, B.Sc., M.Agr., W. I. M. McIntyre, Ph.D., M.R.C.V.S., W. Mulligan, M.Sc., Ph.D., and G. M. Urquhart, Ph.D., M.R.C.V.S... .. .. | 27 | 743 |

**Section of Comparative Medicine with Section of Pathology**

*(JOINT MEETING No. 1)*

*September No.* Meeting April 16, 1958

| | | |
|---|---|---|
| DISCUSSION ON RECENT ADVANCES IN DEMYELINATING DISEASE .. | — | 745 |
| EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS AND ITS IMMUNOCHEMISTRY. By Jack Colover, M.D., M.R.C.P. | — | 745 |
| RECENT ADVANCES IN SWAYBACK. By R. M. Barlow, B.Sc., M.R.C.V.S. | — | 748 |
| DEMYELINATING DISEASE : THE PRESENT SITUATION. By Professor C. E. Lumsden, M.D. .. .. | — | 752 |

**Section of Dermatology**

*March No.* Meeting Oct. 17, 1957

| | | |
|---|---|---|
| CHRONIC GRANULOMA OF FACE. By F. F. Hellier, O.B.E., F.R.C.P. .. | 1 | 173 |
| CHLORACNE. By C. M. Ridley, M.R.C.P. .. .. .. .. | 2 | 174 |
| List of other Cases shown .. .. | 3 | 175 |

*March No.* Meeting Nov. 21, 1957

| | | |
|---|---|---|
| MUCOUS MEMBRANE PEMPHIGOID. By J. H. Allison, M.R.C.P. (for F. Ray Bettley, F.R.C.P.) .. | 3 | 175 |
| PEMPHIGUS VEGETANS. By F. Ray Bettley, F.R.C.P. .. .. .. | 4 | 176 |

*May No.* Meeting Oct. 17, 1957, *contd.*

| | | |
|---|---|---|
| Presidential Address (*By Title*) .. | 5 | 321 |

*May No.* Meeting Nov. 21, 1957, *contd.*

| | | |
|---|---|---|
| SCLEREDEMA [BUSCHKE]. By C. M. Vesey, M.R.C.S., L.R.C.P. (for C. D. Calnan, M.R.C.P.) .. .. | 5 | 321 |
| ŒDEMATOUS SCLERODERMA. By C. D. Calnan, M.R.C.P. .. .. .. | 5 | 321 |
| List of other Cases shown .. .. | 5 | 321 |

*May No.* Meeting Dec. 19, 1957

| | | |
|---|---|---|
| ALOPECIA MUCINOSA (PINKUS). By I. Martin-Scott, M.D. .. .. | 6 | 322 |
| NORMOCHOLESTEROLÆMIC XANTHOMATOSIS. By P. F. Borrie, M.D... | 8 | 324 |
| LIVIDO RETICULARIS. By P. F. Borrie, M.D... .. .. .. .. | 8 | 324 |
| GOUGEROT'S MALADIE TRISYMPTOMATIQUE WITH CRYOGLOBULINÆMIA. By D. C. G. Bett, M.R.C.P. (for Stephen Gold, M.D.) .. .. | 9 | 325 |
| CRYOGLOBULINÆMIA AND RETICULOSIS. By E. N. M. Johnston, M.R.C.P., and H. J. Wallace, M.D., F.R.C.P. | 9 | 325 |
| List of other Cases shown .. .. | 10 | 326 |

*June No.* Meeting Jan. 16, 1958

| | | |
|---|---|---|
| PSORIASIS. By D. I. Williams, F.R.C.P. .. .. .. .. | 11 | 421 |
| RETICULOHISTIOCYTOMA (TYPE CARO/SENEAR). By Denis Sharvill, M.R.C.P. .. .. .. .. | 12 | 422 |
| CUTANEOUS HÆMANGIOMATA AND BONY DEFORMITIES (KLIPPEL-TRENAUNAY and PARKES WEBER SYNDROME). By J. Everall, M.R.C.P., and M. Feiwel, M.R.C.P. (for G. B. Mitchell-Heggs, O.B.E., F.R.C.P.) .. .. .. .. | 13 | 423 |
| List of other Cases shown .. .. | 14 | 424 |

*July No.* Meeting Feb. 20, 1958

| | | |
|---|---|---|
| KAPOSI'S VARICELLIFORM ERUPTION (ECZEMA HERPETICUM) TREATED WITH PREDNISONE. By S. C. Gold, M.D... .. .. .. .. | 15 | 517 |

| | PAGE Sect. | Vol. |
|---|---|---|
| MULTIPLE SKIN NECROSES (ARTERIOLAR)—INGRAM AND SUTHERLAND. By Maurice Garretts, M.B., M.R.C.P. (for W. N. Goldsmith, M.D., F.R.C.P.) .. .. .. | 16 | 518 |
| PRETIBIAL MYXŒDEMA. By K. M. Harvey, M.B. (for Brian F. Russell, M.D., F.R.C.P.) .. .. | 17 | 519 |
| List of other Cases shown .. .. | 18 | 520 |
| *July No.* Meeting March 20, 1958 | | |
| Symposium (*By Title*) .. .. | 18 | 520 |
| List of Cases and Demonstrations .. | 18 | 520 |
| *September No.* Meeting April 17, 1958 | | |
| ANGIOKERATOMA CORPORIS DIFFUSUM. By H. J. Wallace, M.D. | 19 | 707 |
| ECTODERMAL DEFECT WITH SKELETAL ABNORMALITIES. By E. Wilson Jones, M.R.C.P. (for H. J. Wallace, M.D., F.R.C.P.) .. .. .. | 19 | 707 |
| ECZEMA WITH ACANTHOLYTIC BULLÆ. By H. T. H. Wilson, M.R.C.P. .. | 20 | 708 |
| MULTIPLE SEBACEOUS PAPILLOMAS. By P. A. J. Smith, M.B., M.R.C.P. | 21 | 709 |
| GENERALIZED NÆVOID PIGMENTATION. By E. Wilson Jones, M.R.C.P. (for H. J. Wallace, F.R.C.P., and R. J. Cairns, M.R.C.P.) .. .. .. | 22 | 710 |
| ONYCHOLYSIS FROM ADHESIVES. By G. C. Wells, M.R.C.P. .. .. | 23 | 711 |
| CALCINOSIS. By E. N. M. Johnston, M.R.C.P. .. .. .. .. | 23 | 711 |
| LICHEN NITIDUS. By H. T. H. Wilson, M.R.C.P. .. .. .. .. | 24 | 712 |
| *November No.* Meeting April 17, 1958, *contd.* | | |
| List of Cases shown .. .. .. | 25 | 929 |
| *November No.* Meeting May 15, 1958 | | |
| LUPOID ROSACEA. By Brian F. Russell, F.R.C.P. .. .. .. .. | 25 | 929 |
| TUBERCULOSIS VERRUCOSA CUTIS (? WATERBORNE ACID-FAST BACILLUS INFECTION). By J. S. Pegum, M.D. | 26 | 930 |
| EOSINOPHILIC GRANULOMA OF THE FACE OF THE ERYTHEMA ELEVATUM DIUTINUM TYPE. By I. Sarkany, M.R.C.P. (for Louis Forman, M.D., F.R.C.P.) .. .. .. | 26 | 930 |
| List of other Cases shown .. .. | 27 | 931 |
| *November No.* Meeting June 7, 1958 | | |
| Meeting at the General Infirmary, Leeds | | |
| MADURA FOOT (MYCETOMA). By S. T. Anning, M.D., F.R.C.P. .. | 27 | 931 |
| LYMPHOCYTIC LYMPHOMA. By J. T. Ingram, M.D., F.R.C.P. .. .. | 27 | 931 |
| ELASTOMA INTRAPAPILLARE PERFORANS VERRUCIFORME (MIESCHER). By S. T. Anning, M.D., F.R.C.P. | 28 | 932 |
| LUPUS ERYTHEMATOSUS (PROFUNDUS). By J. T. Ingram, M.D., F.R.C.P. | 28 | 932 |
| CASE FOR DIAGNOSIS. ? POIKILODERMA IN A BABY. By F. F. Hellier, O.B.E., F.R.C.P. .. .. .. | 28 | 932 |
| POIKILODERMA AND PIGMENTED LICHEN SCLEROSUS (LUPUS ERYTHEMATOSUS). By J. T. Ingram, M.D., F.R.C.P. .. .. .. | 29 | 933 |
| List of other Cases shown .. .. | 29 | 933 |
| *November No.* Meeting June 26, 1958 | | |
| POLYMYOSITIS AND THYROIDITIS. By Denis Sharvill, M.R.C.P. .. .. | 30 | 934 |
| SCLERODERMA AND CARCINOMA. By Louis Forman, M.D., F.R.C.P., and Hedley Atkins, M.Ch. .. | 31 | 935 |
| BESNIER'S PRURIGO WITH CALCINOSIS. By Brian Russell, M.D., F.R.C.P. | 31 | 935 |
| List of other Cases shown .. .. | 32 | 936 |
| **Section of Endocrinology** | | |
| *January No.* Meeting Oct. 23, 1957 | | |
| THE CLINICAL DIAGNOSIS OF SEX. President's Address by C. N. Armstrong, M.D., F.R.C.P. .. | 1 | 23 |
| *March No.* Meeting July 24, 1957 | | |
| THE PHYSIOLOGICAL CONTROL OF ALDOSTERONE SECRETION [*Abridged*]. By Frederic C. Bartter, M.D. .. .. .. .. | 5 | 201 |
| *March No.* Meeting Nov. 27, 1957 | | |
| IDIOPATHIC HYPOPARATHYROIDISM WITH THIN BONES. By H. K. Ibbertson, M.R.C.P., M.R.A.C.P., and Russell Fraser, M.D., F.R.C.P. | 6 | 202 |
| PRE-TIBIAL MYXŒDEMA FOLLOWING SUBTOTAL THYROIDECTOMY AND RECURRING AFTER SURGICAL EXCISION. By J. H. Briggs, M.B. (for P. M. F. Bishop, D.M.) .. .. | 8 | 204 |
| List of other Cases shown .. .. | 8 | 204 |
| *May No.* Meeting Jan. 22, 1958 | | |
| DISCUSSION ON ENDOCRINE CHANGES IN LIVER DISEASE .. .. .. | 9 | 359 |
| Dr. Sheila Sherlock .. .. | 9 | 359 |
| Dr. J. Lee and Dr. G. W. Bisset .. | 11 | 361 |
| Dr. W. H. J. Summerskill .. .. | 13 | 363 |
| *July No.* Meeting Feb. 26, 1958 | | |
| SOME OBSERVATIONS ON THE MECHANISM OF INSULIN ACTION IN MUSCLE. By P. J. Randle, M.A., Ph.D., M.B., B.Chir., and G. Howard Smith, M.A., B.Sc., Ph.D. | 15 | 551 |

| | PAGE Sect. | Vol. |
|---|---|---|
| CORTICOTROPHIN TESTS IN HIRSUTE WOMEN. By J. D. N. Nabarro, M.D., F.R.C.P., Audrey Moxham, J. D. H. Slater, M.B., M.R.C.P., and G. Walker, M.B., M.R.C.P.. . | 16 | 552 |
| THE IMPORTANCE OF DIFFERENTIAL ASSAY OF URINARY FSH AND ICSH. By P. S. Brown, B.M., M.R.C.P. .. .. .. .. | 18 | 554 |
| *July No.* Meeting March 26, 1958 | | |
| THE URINARY EXCRETION OF ŒSTROGENS, PREGNANEDIOL AND PITUITARY GONADOTROPHINS DURING THE MENSTRUAL CYCLE [*Abridged*]. By J. B. Brown, M.Sc., Ph.D., A. I. Klopper, B.Sc., Ph.D., M.B., M.R.C.O.G., and J. A. Loraine, M.B., Ph.D., M.R.C.P.(Ed.) .. | 20 | 556 |
| SOME EFFECTS OF 17α-ETHYL-19-NORTESTOSTERONE IN MAN. By F. T. G. Prunty, M.D., F.R.C.P., R. V. Brooks, Ph.D., Barbara E. Clayton, M.D., Ph.D., and R. R. McSwiney, M.B. .. .. .. | 21 | 557 |
| SOME OBSERVATIONS ON ADRENOCORTICOTROPHIN IN BLOOD. By Barbara E. Clayton, M.D., Ph.D. | 22 | 558 |
| THE NEURAL INTERMEDIATE LOBE HORMONE ("B"). By F. W. Landgrebe, D.Sc., and G. M. Mitchell, M.B. .. .. .. | 24 | 560 |
| *September No.* Meeting April 23, 1958 | | |
| CROHN'S DISEASE WITH FEATURES SUGGESTING ADDISON'S DISEASE. By D. Mattingly, M.B., M.R.C.P. (for Professor F. T. G. Prunty, M.D., F.R.C.P.) .. .. .. | 27 | 719 |
| CONN'S SYNDROME. By P. K. M. Barrett, M.B., R. I. S. Bayliss, M.D., F.R.C.P., and J. R. Rees, M.B., M.R.C.P. .. .. .. | 28 | 720 |
| CŒLIAC DWARFISM, WITH ANÆMIA and OSTEOMALACIA. By O. Garrod, M.D. .. .. .. .. | 30 | 722 |
| FEMALE PSEUDOHERMAPHRODITISM. By H. K. Ibbertson, M.R.C.P., M.R.A.C.P., and Russell Fraser, M.D., F.R.C.P. .. .. .. | 31 | 723 |
| *September No.* Meeting May 28, 1958 | | |
| Discussion (*By Title*) .. .. .. | 32 | 724 |
| *December No.* Meeting Oct. 22, 1958 | | |
| THE INTERPRETATION OF HORMONAL ABNORMALITIES. President's Address by Professor F. T. G. Prunty, M.D., F.R.C.P. .. .. .. | 33 | 1073 |

## Section of Epidemiology and Preventive Medicine

| | PAGE Sect. | Vol. |
|---|---|---|
| *March No.* Meeting Oct. 18, 1957 | | |
| SYMPOSIUM ON OPERATIONAL RESEARCH IN THE NATIONAL HEALTH SERVICE .. .. .. .. | 1 | 139 |
| Dr. J. N. Morris .. .. .. | 1 | 139 |
| Dr. J. A. H. Lee, Dr. F. M. Martin | 2 | 140 |
| Mr. Louis Moss .. .. .. | 4 | 142 |
| *March No.* Meeting Nov. 15, 1957 | | |
| SYMPOSIUM ON EVENTS IN PREGNANCY IN RELATION TO DISEASE AND DEFECTS IN THE INFANT .. .. | 8 | 146 |
| Dr. Alison D. McDonald .. | 8 | 146 |
| Dr. R. G. Record .. .. .. | 9 | 147 |
| Dr. J. A. McCredie Smith .. | 11 | 149 |
| *April No.* Meeting Jan. 17, 1958 | | |
| SYMPOSIUM ON WEATHER AND DISEASE | 13 | 259 |
| Mr. R. G. Veryard.. .. .. | 13 | 259 |
| Mr. E. N. Lawrence .. .. | 15 | 261 |
| Dr. P. J. Lawther .. .. .. | 16 | 262 |
| Dr. B. B. Waddy .. .. .. | 18 | 264 |
| *October No.* Meeting Feb. 21, 1958 | | |
| SYMPOSIUM ON EPIDEMIOLOGICAL RISKS OF ANTIBIOTICS .. .. | 21 | 807 |
| Dr. E. J. L. Lowbury .. .. | 21 | 807 |
| Dr. J. B. Selkon .. .. .. | 24 | 810 |
| Dr. H. Williams Smith .. .. | 26 | 812 |
| *December No.* Meeting May 16, 1958 | | |
| Joint Meeting with the Fever Group of the Society of Medical Officers of Health | | |
| SYMPOSIUM ON THE ASIAN INFLUENZA EPIDEMIC, 1957 .. .. .. | 29 | 1009 |
| Dr. A. M.-M. Payne .. .. | 29 | 1009 |
| Dr. J. C. McDonald .. .. | 36 | 1016 |

## Section of Experimental Medicine and Therapeutics

| | PAGE Sect. | Vol. |
|---|---|---|
| *February No.* Meeting Oct. 8, 1957 | | |
| METHODS OF MEASURING PULMONARY DIFFUSING CAPACITY AND THEIR SIGNIFICANCE. By Robert Marshall, M.D., M.R.C.P. .. .. .. | 1 | 101 |
| OLIGOPNŒA [*Abridged*]. By P. Hugh-Jones, M.A., M.D., M.R.C.P. .. | 4 | 104 |
| MECHANISMS OF AIRWAY OBSTRUCTION IN EMPHYSEMA AND ASTHMA. By E. J. M. Campbell, M.D., Ph.D., M.R.C.P. .. .. .. .. | 8 | 108 |
| *June No.* Meeting Dec. 10, 1957 | | |
| GASTRIC FUNCTION .. .. .. | 11 | 461 |
| THE RATE OF GASTRIC EMPTYING IN PATIENTS WITH DUODENAL ULCER. By J. N. Hunt, M.D., D.Sc. .. | 11 | 461 |

| | PAGE Sect. | Vol. |
|---|---|---|
| I. Observations on the Cardiac and Pyloric Sphincters in Man. By M. Atkinson, M.D., M.R.C.P., D. A. W. Edwards, M.D., M.R.C.P., A. J. Honour, and E. N. Rowlands, M.D., F.R.C.P. .. .. .. | 12 | 462 |
| II. Mechanisms of Gastro-œsophageal Reflux in Hiatus Hernia. By M. Atkinson, M.D., M.R.C.P., D. A. W. Edwards, M.D., M.R.C.P., A. J. Honour, and E. N. Rowlands, M.D., F.R.C.P. .. .. .. | 13 | 463 |
| The Gastric Mucosa in Hypochromic Anæmia. By N. F. Coghill, M.A., M.B., M.R.C.P., and A. Wynn Williams, M.D., D.C.P.Lond. .. .. .. | 14 | 464 |
| *August No.* Meeting Feb. 5, 1958 | | |
| Symposium on Hæmoglobin .. | 15 | 639 |
| Professor C. Rimington .. .. | 15 | 639 |
| Dr. A. C. Allison .. .. .. | 17 | 641 |
| Dr. V. M. Ingram .. .. | 21 | 645 |
| Dr. J. H. Walters .. .. .. | 22 | 646 |
| *September No.* Meeting March 11, 1958 | | |
| Acquired Hæmolytic Anæmia. President's Address by Professor J. V. Dacie, M.D., F.R.C.P. .. .. | 25 | 699 |
| **Section of Experimental Medicine and Therapeutics with Section of Neurology** (*JOINT MEETING No.* 2) | | |

| List of other Cases shown .. .. | 18 | 296 |
| *June No.* Meeting Jan. 24, 1958 | | |
| DISCUSSION ON THE PREVENTION OF ACCIDENTS IN CHILDHOOD.. .. | 19 | 395 |
| Dr. C. A. Boucher .. .. | 19 | 395 |
| Mr. D. MacG. Jackson .. .. | 20 | 396 |
| Professor S. D. M. Court, Dr. L. Colebrook, Dr. D. MacCarthy | 26 | 402 |
| *September No.* Meeting Feb. 28, 1958 | | |
| Meeting at the Hospital for Sick Children, Great Ormond Street, London | | |
| ULCERATIVE COLITIS IN CHILDHOOD AND A FOLLOW-UP STUDY [*Summary*]. By B. Schlesinger, O.B.E., M.D., F.R.C.P., and J. Platt, B.A., B.M., B.Ch., M.R.C.P. .. .. | 27 | 733 |
| List of Demonstrations .. .. | 29 | 735 |
| *September No.* Meeting March 28, 1958 | | |
| RECURRENT HYPERTROPHIC POLYNEURITIS. By Philip R. Clay, M.R.C.P. (for Hugh Ellis, M.D.) | 29 | 735 |

| | PAGE Sect. | Vol. |
|---|---|---|
| SYNDROME OF OSTEOPOROSIS, CALCIFICATION OF THE BASAL GANGLIA, DWARFISM, MENTAL RETARDATION AND VENTRICULAR SEPTAL DEFECT. By P. F. Benson, M.R.C.P. (for R. E. Bonham Carter, F.R.C.P.) .. | 30 | 736 |
| MARTIN'S SYNDROME DIAGNOSED BY FINDING HEINZ BODIES IN THE PERIPHERAL BLOOD. By D. G. Cottom, M.R.C.P. (for R. E. Bonham Carter, F.R.C.P.) .. | 32 | 738 |
| JUVENILE DISSEMINATED SCLEROSIS. By R. H. R. White, M.A., M.B., M.R.C.P., D.C.H. (for P. R. Evans, M.D., M.Sc., F.R.C.P.) .. | 33 | 739 |
| VITAMIN-D-RESISTANT RICKETS WITH CRANIOSTENOSIS. By K. Hugh-Jones, M.D., M.R.C.P. (for C. F. Harris, M.D., F.R.C.P.) .. .. | 34 | 740 |
| THORACIC NEUROBLASTOMA, TREATED WITH VITAMIN $B_{12}$. By O. D. Fisher, M.R.C.P. .. .. .. | 36 | 742 |
| HYPERTROPHY OF RIGHT CALF MUSCLES. By O. D. Fisher, M.R.C.P. .. .. .. .. | 36 | 742 |
| L.E. CELL PHENOMENON ASSOCIATED WITH CHRONIC HEPATITIS. By C. Upjohn, M.D. (for J. N. O'Reilly, D.M.) .. .. .. .. | 36 | 742 |
| *November No.* Meeting April 18, 1958 | | |
| BLADDER NECK OBSTRUCTION. By D. Innes Williams, F.R.C.S. .. | 37 | 957 |
| *Bacillus fæcalis alcaligenes* SEPTICÆMIA IN THE NEWBORN. By S. A. Doxiadis, M.D., with the co-operation of M. Pavlatou, M.D., and O. Chryssostomidou, M.D. . | 39 | 959 |
| CUTANEOUS GANGRENE. By K. W. Lovel, M.R.C.P. .. .. .. | 42 | 962 |
| *December No.* Meeting June 28, 1958 | | |
| Meeting Held at Bristol | | |
| THE TREATMENT OF PHENYLKETONURIA. By F. S. W. Brimblecombe, M.D., and Margaret E. R. Stoneman, M.B. .. .. .. .. | 45 | 1019 |
| HYPERBILIRUBINÆMIA IN PREMATURE INFANTS TREATED BY EXCHANGE BLOOD TRANSFUSION. By Beryl D. Corner, M.D., F.R.C.P. .. .. | 45 | 1019 |
| HEART FAILURE IN INFANTS. By K. Simpson, M.D. .. .. .. | 48 | 1022 |
| A COMMON DENOMINATOR IN THE RECURRENT PAINS OF CHILDHOOD. By John Apley, M.D. .. .. | 49 | 1023 |
| THE VASCULAR FACTOR IN BIRTH INJURY. By A. V. Neale, M.D., and H. Urich, M.D. .. .. .. | 50 | 1024 |
| PERITONEAL DRAINAGE IN THE TREATMENT OF HYDROCEPHALUS. By G. L. Alexander, B.Sc., M.D., F.R.C.S., D. G. Phillips, M.B., F.R.C.S., D.L.O., and A. Hulme, M.B., F.R.C.S. .. .. .. | 51 | 1025 |
| SOME OBSERVATIONS ON AVIAN OSTEOPETROSIS. By J. R. Holmes, M.V.Sc., Ph.D., M.R.C.V.S. .. | 52 | 1026 |
| REGIONAL ILEITIS IN CHILDREN. By C. H. Talbot, F.R.C.S. .. .. | 53 | 1027 |

## Section of Pathology

| | PAGE Sect. | Vol. |

| Professor Haddow, Dr. Joseph Burchenal .. .. .. | 16 | 416 |
| Dr. John F. Wilkinson .. .. | 17 | 417 |
| Dr. Bodley Scott, Dr. Wiltshaw, Dr. Frei .. .. .. .. | 18 | 418 |
| Dr. Farber, Professor Haddow, Dr. Custer, Dr. Bodley Scott, Dr. Frei .. .. .. .. | 19 | 419 |
| Dr. Burchenal, Dr. Skipper, Professor Haddow .. .. .. | 20 | 420 |
| *July No.* Meeting Jan. 8, 1958 | | |
| Meeting held at St. Mary's Hospital, London | | |
| List of Operations, Demonstrations and Short Papers .. .. .. | 21 | 503 |
| *July No.* Meeting Feb. 5, 1958 | | |
| DISCUSSION ON SMALL BOWEL OBSTRUCTION [*Abridged*] .. .. | 21 | 503 |
| Mr. Robert V. Cooke .. .. | 21 | 503 |
| Mr. P. T. Savage .. .. .. | 25 | 507 |
| *September No.* Meeting March 5, 1958 | | |
| DISCUSSION ON HAND INJURIES .. | 27 | 713 |
| Dr. M. Iselin .. .. .. | 27 | 713 |
| Mr. John N. Barron .. .. | 29 | 715 |
| Mr. L. W. Plewes .. .. .. | 30 | 716 |
| *October No.* Meeting April 2, 1958 | | |
| THE POST-AURICULAR WOLFE GRAFT AND ITS USE IN THE TREATMENT OF MALIGNANT ULCERATION OF THE FACE. By J. C. M. Currie, M.B., B.Chir. (for Alan Hunt, M.Ch.).. | 33 | 815 |
| PERSISTENT VARICOSE VEINS WITH SPECIAL REFERENCE TO THE VARICOSE TRIBUTARIES OF THE SUPERFICIAL FEMORAL AND POPLITEAL VEINS. By Harold Dodd, Ch.M., F.R.C.S. .. .. .. .. | 35 | 817 |
| Film (*By title*) .. .. .. .. | 38 | 820 |

## United Services Section

| | PAGE Sect. | Vol. |
|---|---|---|
| *January No.* Meeting Oct. 3, 1957 | | |
| THE PROBLEM OF NOISE IN THE ROYAL AIR FORCE. By Wing Commander P. F. King, F.R.C.S.Ed., D.L.O., and Flight Lieutenant R. P. Gannon, B.Sc., M.B., Ch.B. .. | 1 | 45 |
| *February No.* Meeting Dec. 5, 1957 | | |
| SUBMARINE MEDICINE ON U.S.S. NAUTILUS AND U.S.S. SEAWOLF. By Lt. Cdr. John H. Ebersole .. | 9 | 63 |
| *June No.* Meeting March 6, 1958 | | |
| DISCUSSION ON INFLUENZA .. .. | 21 | 447 |
| Major R. J. C. Hart, R.A.M.C. .. | 21 | 447 |
| Surgeon-Major G. H. Bulow .. | 24 | 450 |
| Lt.-Col. R. M. Johnstone, M.B.E., M.C., R.A.M.C.. .. .. | 25 | 451 |
| Colonel T. A. Pace, O.B.E., M.D., B.Sc., D.P.H. .. .. .. | 26 | 452 |
| *October No.* Meeting June 5, 1958 | | |
| DISCUSSION: UNDERWATER EMERGENCIES IN THE ROYAL NAVY .. .. | 29 | 821 |
| Surg. Cdr. S. Miles, R.N.. .. | 29 | 821 |
| Surg. Lt. R. J. W. Lambert, R.N. | 32 | 824 |
| Surg. Lt. Cdr. J. S. P. Rawlins, R.N., M.B.E. .. .. .. | 36 | 828 |
| *December No.* Meeting Oct. 2, 1958 | | |
| A REVIEW OF HÆMODIALYSIS IN RENAL FAILURE AND SOME POINTS IN THE DIAGNOSIS OF ACUTE RENAL FAILURE. By A. M. Joekes, M.R.C.P. .. .. .. .. | 39 | 1069 |
| Paper (*By Title*) .. .. .. | 40 | 1070 |
| EXPERIENCES WITH THE KOLFF TWIN COIL ARTIFICIAL KIDNEY AT THE RENAL UNIT, PRINCESS MARY'S ROYAL AIR FORCE HOSPITAL, HALTON. By Group Captain R. C. Jackson, M.R.C.P.Ed. .. .. | 41 | 1071 |

## Section of Urology

| | PAGE Sect. | Vol. |
|---|---|---|
| *March No.* Meeting Oct. 24, 1957 | | |
| THE CALCIUM-CONTAINING RENAL STONE [*Abridged*]. President's Address by Leslie N. Pyrah, M.Sc., Ch.M., F.R.C.S. .. .. .. | 1 | 183 |
| *March No.* Meeting Nov. 28, 1957 | | |
| List of Specimens shown .. .. | 18 | 200 |
| *May No.* Meeting Jan. 23, 1958 | | |
| URINARY COLLOIDS [*Abstract*]. By N. F. Maclagan, M.D., D.Sc., F.R.C.P. .. .. .. .. | 19 | 327 |
| BILATERAL ORCHIDOPEXY AND FERTILITY. By J. H. Carver, T.D., F.R.C.S. .. .. .. .. | 20 | 328 |

| | PAGE Sect. | Vol. |

## Comparative Aspects in Virology

### PRESIDENT'S ADDRESS

By J. B. Brooksby, D.Sc., Ph.D., M.R.C.V.S.

#### Introduction

An interesting feature of virology is that the overlap of interest between the medical and veterinary fields is perhaps greater than in many other basic studies of human and veterinary medicine. Several diseases occur in both man and animals, but this does not explain why illustrations in medical texts on virology are frequently drawn from veterinary medicine and vice versa.

Two major aspects only will be discussed—modified strains and their use in immunization, and basic studies on structure, especially with regard to biological properties.

#### Modified Strains and Their Use in Immunization

The use of modified strains for immunizing purposes is one of the oldest concepts in virology. Since the number of instances of use of such strains is increasing, particularly in the veterinary field, some consideration of the nature and properties of modified strains seems to be necessary.

The selection of naturally occurring strains of low virulence, such as vaccinia, is historically ancient. All virologists are acquainted with variation in virulence as between different field strains of viruses. In some cases this may be manifested in a virus which attacks more than one host species, as normal virulence for one species and almost complete non-infectivity for another. An example of this phenomenon is the cattle adaptation and swine adaptation of some strains of foot-and-mouth disease. This has its epidemiological significance in outbreaks of disease confined to cattle and to swine respectively. Such strains can be regarded as naturally modified strains. There is here a natural method of genetic selection of the strain, due to the factors of difference in the hosts. No such method would seem to exist with viruses with a single host, and it is therefore left to the virologist to arrange the conditions so that if modifications arise, the environment will favour their survival. In time, the strain will become relatively homogeneous in respect of the characters desired. In this paper the various processes of modification are considered more from the practical point of view than from the fundamental principles involved.

The simplest technique for production of modified strains, which hardly seems to imply

actual interference by the virologist, is the selection of strains of low virulence which either exist in the wild strain or are very readily produced from it. Examples of these are the Newcastle disease vaccine strains used in mass immunizing procedures in the U.S.A. and the modified poliomyelitis strains of Sabin (1955) and Koprowski (1955). Sabin passaged virus in tissue culture and segregated variants, first by a dilution technique, and finally by isolation of individual plaques. The tests of such strains have been discussed at length at Geneva, and perhaps the most important criterion required of them, apart from lowered initial virulence, is that strains isolated from vaccinated individuals must still show some attenuation. The general feeling is against wide use of such modified strains until greater safeguards can be devised.

The second category of modified strains are those which have been artificially produced by adaptation of virus to abnormal hosts, or to tissues not commonly attacked. There is a substantial literature on the strains which have been produced in this way, but the mechanism of the process involved is by no means clear, and indeed there is little information on which techniques may be most effectively used. Some of the factors which may be important in the process of modification of a strain will now be considered.

(1) *The preservation of the antigenic identity of the virus during modification.*—There have been relatively few suggestions that the antigenic identity of a virus has been altered during modification. Hirst (1947) in dealing with mouse-adapted strains of influenza virus demonstrated that two lines derived in mice were antigenically dissimilar, and that each was different from the parent strain from which they were derived. On the other hand the "O" and "D" strains of Burnet and Bull (1943), although different in a hæmagglutinating capacity were antigenically similar. Edwards (1949) suggested that different goat-adapted strains of rinderpest virus had antigenically dissimilar constitution, but the dissimilarity noted might have been due to other factors. Brotherston (1955) with the same virus, compared the antigens of cattle, goat and rabbit strains and believed them to be identical.

In the process of modification it would seem that while many of the characters are labile, the antigenic constitution is remarkably stable. Does this suggest that the antigenic constitution depends on what might be termed the core of the virus, rather than on the outer covering—in terms of Crick and Watson's (1956 and 1957) hypothesis on the ribonucleic acid (R.N.A.) rather than the protein envelope?

(2) *Alteration in tissue tropism of the virus.*—It has sometimes been stated that modified strains might be expected to give their best results if they produced an inapparent infection in a tissue which the virus usually infects. Intranasal strains in influenza, and intestinal strains in poliomyelitis follow this dictum. On the other hand adaptation to another host frequently involves also a change in the tissue tropism of the virus, for example in the neurotropic strains of African horse sickness and of yellow fever. If, then, infection of the usual host takes place it may not involve the tissue normally associated with the infection, but rather produce a new form of the disease in another tissue. Schneider (1956) has described muscular lesions in cattle after inoculation of a myotropic strain of the virus of foot-and-mouth disease modified by passage in mice. If this trend to altered tropism were carried too far, multiplication of the virus at unusual sites might have unfortunate effects in vaccinated animals.

(3) *Significance of age of host in reaction to modified virus.*—Viruses may produce different effects in hosts of different ages. In human medicine the classic example is the effect of rubella on the fœtus. In veterinary medicine the virus of foot-and-mouth disease in the young animal may produce acute lesions in both cardiac and skeletal muscle leading to death. With modified strains there has already been indication of untoward effects. In vaccination of swine with lapinized swine fever vaccine, fœtal defects and increased number of stillbirths were observed, when swine were vaccinated in early pregnancy (Young, 1952). These defects were somewhat milder than might have been expected with an unmodified virus. From the laboratory point of view it is therefore obvious that adequate tests of modified strains in animals of all ages are necessary.

(4) *Fixity of modified strains.*—The fixity of the strain is of primary importance. For some viruses the margin between loss of infectivity on the one hand and loss of immunizing power on the other is a small one, and it is necessary to make sure that the strain will retain its properties once it has been altered. It is difficult to be sure whether some of the field

reports of reversion to full virulence are actually due to alteration in character of the strain or to increased susceptibility of the particular group of animals inoculated. Latent infections may also be brought to light by inoculation of a modified strain and complicate the situation. Occasionally the lapinized swine-fever vaccine gives severe reaction in an inoculated herd. There is no record of examination of the virus in the laboratory following such an event, and it is therefore impossible to determine whether the difficulty has arisen with the virus or with the host. In poliomyelitis, Dick and his colleagues (Dane *et al.*, 1957) have shown quite clearly an increase in virulence for monkeys of the strain after passage through the intestine of children. In the case of rinderpest virus there is clear indication that strains which are quite certainly fixed in character, for example the Nakamura III strain, may produce quite a high mortality in hypersensitive cattle. This has been described for Japanese Black cattle and also for some Korean breeds (Nakamura and Kuroda, 1942). The fixity of this strain was controlled by serial passage in cattle when ten passages had no effect on increasing virulence for cattle (Nakamura *et al.*, 1943). Brotherston (1951) claimed to be able to increase virulence slightly by alternate rabbit and cattle passages.

(5) *Reproducibility of strain modification.*—Reproducibility of the course of modification is of more fundamental interest. In the strains of virus which have been used for immunization in the field, it has frequently been the custom to accept the strain in the phase to which it has been developed, and not to enquire too closely into the stages in its attenuation. The modification of a strain does not seem to mean change in only one character, but rather a summation of changes in several associated characters. It is therefore hardly surprising that the alteration from fully virulent strain to the characteristic modified strain should be a slow process.

One of the most interesting examples where the attenuation of a strain for several different species has been described is the work on the Flury strain of rabies. In its first form this strain was suitable for use in dogs, and of course has had a wide use in that species. Vaccination of cattle with this strain was found to produce clinical signs of rabies. Further serial passage produced strains of lower virulence for various laboratory animals (guinea-pigs and hamsters), and finally a stage was reached at which cattle could be inoculated with safety. In man inoculation of the more attenuated strain followed by the less attenuated strain will give a good immunity.

(6) *Simultaneous modification for more than one host.*—Wide host range is essentially a problem which is of veterinary interest in respect of modified strains. The problem of naturally species-adapted strains in foot-and-mouth disease has already been mentioned. The corollary is the adapted strain which has a lowered pathogenicity for cattle but not for swine. A case in which a modified strain had this property was recently observed by Sellers (unpublished) in our laboratory. This particular strain had been passaged in mice and the virulence greatly reduced for cattle. It was, however, still fully virulent for swine. The second observation, on another strain of another type, had fortuitous success in that the strain had been rendered non-infective for swine and only almost so for cattle. This strain had been passaged in a variety of experimental hosts including both mice and eggs.

## Factors Influencing the Control of Modification of Strains

The problem of estimation of the degree of attenuation which has been achieved is dealt with much more readily in veterinary than in human medicine. It is possible in the last analysis to test the strain in the animal which is the natural host, and it is therefore not necessary to base the probable effect on experimental results in nearly related species. This does not mean that a correlation should not be sought between the results in the natural host and the results in other species which could be used as indicators in the degree of attenuation of the strain. The usefulness of such indicators during the serial passages leading to attenuation is obvious. The detailed history of the attenuation of a strain gives confidence in its probable behaviour.

It is important to consider the role of the host, as the attenuated strain is conceived as invading and multiplying in the vaccinated host. This invasion and multiplication, like any other infection, will be governed by the host susceptibility and invasive power of the virus. Host susceptibility can be observed to vary quite widely in the reactions of individuals to viruses which have not been attenuated. The variation in susceptibility of the host might be expected to become more obvious with attenuated strains of poor invasiveness. Thus it might well be that strains differing quite widely in attenuation produce little difference in

the number of animals infected in given groups of known susceptible animals, if it is once accepted that a small percentage, say 5% are hypersensitive. It must be noted that with non-attenuated strains it is the animals of low susceptibility, resistant animals, which are most readily observed. With the attenuated strains at the time of vaccination the animals of high susceptibility are more obvious. When the time comes for the animals to be challenged it is of course obvious again which animals have been of low susceptibility and fail to become infected by the attenuated strain. Observations on a modified strain of the virus of foot-and-mouth disease illustrate these points. Through a number of serial passages this strain appeared constantly to infect about one out of eight cattle inoculated intradermally in the tongue. In an experiment using a virus dose 1/100 that which infected one of eight animals, two of eight became infected. It seems that host susceptibility rather than degree of attenuation is the operative factor. At the same time this strain failed to immunize about one out of eight animals inoculated, perhaps due to a natural resistance in such cattle.

A possible solution to the problem of infectivity of attenuated strains lies in the administration of the virus by a route other than into the most susceptible tissue. This solution has been tried with a number of viruses, notably with that of infectious laryngo-tracheitis and those neurotropic viruses for which a modified strain is available, such as rabies, and Teschen disease. Modification of the route, however, may not always give the desired result, and cannot be relied upon to make an attenuated strain safer than it otherwise would be in the unattenuated form. A number of workers have drawn attention to the fact that the various respiratory viruses given intramuscularly produce respiratory infection, and some attenuation must be achieved before giving the virus by such a route. On the other hand some strains of the virus of foot-and-mouth disease have been demonstrated to require more than 100,000 times as much virus in order to set up infection by the subcutaneous route as by the intradermal tongue route (Henderson, 1952). These strains were not attenuated and it was found that some animals which failed to react following subcutaneous inoculation did not develop an immunity. The use of an attenuated strain by a route other than the usual one, may fail as an immunizing procedure unless there is some characteristic of the strain which allows it to multiply either at site of inoculation or elsewhere in the body. Very little is known of the tissue propensities of the attenuated strains of most viruses. Research workers have been mainly interested in the fact that they failed to produce the typical disease in the tissue most commonly affected. Nevertheless it would seem to be of great importance to determine where and to what extent attenuated strains multiply in the tissue of the vaccinated host. In work at present in progress in foot-and-mouth disease virus, this stage is about to be reached. Following the work of Skinner (1951) cattle strains of virus have been adapted to the baby mouse and then subsequently to adult mice, which are inoculated intramuscularly. The disease in the mouse is characterized by degeneration of skeletal and cardiac muscle. Skinner (unpublished) has made some interesting experiments on guinea-pigs using such strains. The dermotropic character of the virus in guinea-pigs disappears gradually and progressively on mouse passage. When this modified virus is inoculated intramuscularly, muscular lesions may be produced in young (2–3 weeks) guinea-pigs. In older guinea-pigs, however, no clinical signs are observed, but in both age groups an immunity to intradermal challenge is developed. The dose of virus required to produce this immunity is small, less than 100 I.D.50 for the mouse. Such strains have not yet been fully tested in cattle, although, as in guinea-pigs, their dermotropic characters have been reduced to the point when less than 15% of cattle develop lesions following intradermal inoculation into the tongue. Some strains passaged in eggs also lose their ability to produce clinical infection in cattle.

There may be need for caution in the use of myotropic strains; as mentioned earlier, Schneider obtained lesions in heart and tongue muscles after inoculation of a strain passaged 296 times in mice. Only further experimental work will indicate the probable role of such strains.

Other modified strains in foot-and-mouth disease have been the mouse neurotropic strains of Nagel (1937), and of course the guinea-pig strains which are passaged by the epithelial route. Immunization of cattle by such strains has not been successful.

In at least five cases in veterinary medicine virus passaged in the chick embryo have given attenuated strains which have been used in the field. In foot-and-mouth disease many attempts were made to adapt the virus to the egg before the successful results of Traub and Schneider (1948). Such egg-passaged viruses in foot-and-mouth disease have not generally been regarded as giving a good immunity in cattle, though some results which were limited to groups of two cattle, indicate possible immunizing value. The results quoted earlier of exposure of animals to attenuated strains were, however, produced with a modified strain which, for a great part of its history, had been passaged in eggs.

Skinner (1954) and Gillespie (1954) independently made observations of passage of foot-

and-mouth disease in the young chick. No work has been done on the infectivity of these strains for cattle until recently, when a report appeared on the non-infectivity of a chick strain after 25 serial passages.

I have spoken of the advantages of testing attenuated strains in the susceptible host, but other methods in addition would be useful in screening tests. Pay and Sellers have recently attempted to correlate the cytopathic changes with the pathogenicity of the strain in the natural host species. The results of this in poliomyelitis have been equivocal. In foot-and-mouth disease a range of cells has been used from different hosts—bovine epithelium, bovine kidney, calf kidney, pig kidney—and the cytopathic changes have been correlated with the pathogenicity of the strain in cattle. Strains not pathogenic for cattle have a low cytopathogenicity in bovine and calf kidney, but not necessarily so in pig kidney. Extension of these correlations will be most valuable in observing the alteration of strains during extensive serial passages, which have so far been necessary for attenuation.

The list of veterinary viruses for which attenuated strains are obtainable is already long and appears to be growing. Rinderpest, bluetongue, swine fever, African horse sickness, rabies, distemper, Newcastle disease, fowlpox and infectious bovine rhinotracheitis have all been published, and several more are I believe in course of preparation for publication. The usefulness of most of these vaccines have been assessed in the field, and it is difficult to generalize on the results in a way that one would wish.

With some of the modified strains, notably rinderpest, there has been an acceptance of a calculated risk of producing clinical signs of the disease in a proportion of the animals inoculated. For estimation of efficacy of vaccines, antibody studies of the inoculated animals before and after administration of the strain are indicated, and some very precise idea of the challenge to which the animals are exposed. This would help in comparing the attenuated strains among themselves and also in relation to inactivated vaccines. The laboratory control of these vaccines is by no means easy, and once a strain has been shown to be reasonably safe, it has usually been the practice to accept it without too many further questions as to its origin and whether it could be further modified to increase its efficacy.

## Structure of Virus in Relation to Biological Properties

There is a long list of viruses which show complexity of structure, in that a number of specific particles can be separated from viral suspensions. These particles range from those which are considered as the fully infective particle to smaller ones, whose properties are mainly serological, ranging from hæmagglutination down to complement fixation. The term soluble antigen, which was originally applied by Craigie in vaccinia, has been carried through to the smaller viruses in which the solubility of the small particle is hardly a criterion of differentiation from the large particle. According to the view of the worker, both the smaller and larger could be regarded as either soluble or insoluble. There is a tendency now to refer to the particles in terms of their properties rather than by an arbitrary definition of solubility. The list of viruses in which such complexity exists is a long one, outstanding examples being:

Vaccinia. Mumps. Herpes. Influenza. Yellow fever. Various insect-transmitted encephalitides. Dengue. Poliomyelitis. Foot-and-mouth disease. Newcastle disease virus. Vesicular stomatitis.

Bradish, Brooksby, Dillon and Norambuena (1952) described studies of the sedimentation properties of the virus of foot-and-mouth disease. This work has been extended (Brooksby, 1953, and Bradish, unpublished) and the following summarizes the present position.

In a suspension of the virus of foot-and-mouth disease there are two main particles, separable in the ultracentrifuge:

(1) 70 S component contributing 50% of the complement-fixing activity and most of the infectivity, and

(2) 8 S contributing the other 50% of the complement-fixing activity and less than 1/10,000 of the infectivity.

Another particle of intermediate and indeterminate size is the subject of current research.

In fresh unfractionated virus preparation, the two major components exist in a proportion such that each contributes 50% of the total complement-fixing activity. On storage and on

more violent treatment disintegration of the large component takes place with decrease of infectivity, and a relatively higher proportion of complement-fixing activity appears in the small component fraction.

Heat treatment produces this effect within a few minutes. The intermediate component appears in sedimented larger material. Deposits from the original virus suspension resuspended and recentrifuged yield supernatants which have considerable complement-fixing activity. It would appear that this intermediate component is shed from the surface of the large particle, although complete disintegration of a small proportion of the total large particle present, might account for the results. In addition to the criterion of size, the components may be differentiated by serological methods. The large component is almost completely type specific in complement-fixation tests, while the small component is almost completely without type specificity. The intermediate component has a serological specificity which is intermediate between that of the large and small materials. When, however, the large particle is disintegrated by less gentle means, such as heating, the small component is not type specific. A possible hypothesis is that all the small component contributing to the structure of the large, is originally type specific, but that it is denatured on storage or by heat treatment, to yield small component of the more typical poor specificity. One interesting point here, to which I shall refer later, is that the small components of two sub-types, e.g. two sub-strains of type "O" corresponding in influenza to two sub-strains of type "A" such as A′ and Asian, can be differentiated by serological methods. This is surprising when it is not possible to differentiate sharply between small components derived from two strains of entirely different types (e.g. O and A). The relationship between the large component and the small component has recently been demonstrated in a new and very pretty way by Brown and Crick (1957). First, when virus and serum diffuse towards each other in agar gels, two lines are formed. These correspond to the precipitin zone of the large 20 m$\mu$ particle, and the small 7 m$\mu$ particle, for if the separate fractions are similarly diffused towards each other, adjacent to the test on unfractionated virus, the lines merge with the appropriate line in the double line of the unfractionated material. Tests with the separated components of the virus system seemed at first to show an anomaly between the gel diffusion result and the result of complement-fixation tests, for in gel diffusion tests small component gave a line only with homotypic serum, and not with heterotypic also, as might have been expected from the complement-fixation test. When an agar gel diffusion test was carried out with small component, to which had been added heterotypic serum, no line was formed, indicating combination of small component and heterotypic antibody. With the large component, addition of heterotypic serum had no effect on the production of a line. A simple expression of the result is to say that the combination of small component with homotypic antibody is precipitating and with heterotypic it is not. Brown and Crick (1958) have also been able to demonstrate the heat disintegration of virus by means of agar gel tests. They have also obtained indication of probable existence of two separate antibodies to the large and small component respectively in antiviral sera. Further analysis of this kind should be most fruitful. It is interesting to note that in published pictures of myxoma virus reacting with its anti-sera in this way, three lines have been observed, and in the case of swine fever, two lines (Mansi, 1957).

The work which is most directly comparable with our own on foot-and-mouth disease is that of Schäfer (1957) on fowl plague virus and of the South African group, Kipps *et al.* (1957) on poliomyelitis, rabies and a number of veterinary viruses indigenous to South Africa. Comparison of the findings of these workers with those on foot-and-mouth disease is interesting. Schäfer and Munk (1952) earlier differentiated two particles, the virus and the soluble antigen. In later work Schäfer obtained from a purified elementary body suspension (particles of 70–80 m$\mu$) two other small particles, by shaking the elementary bodies with ether. The two particles were the 30 m$\mu$ hæmagglutinin, and the smaller g-antigen, the bound ("gebunden") antigen, with a diameter of 10–15 m$\mu$. The hæmagglutinin is similar in properties to the elementary particle except that it has no infectivity. Both the hæmagglutinin and the virus particle are precipitated by anti-viral and anti-hæmagglutinin in rabbit sera. The g-antigen on the other hand gives no precipitation with anti-viral or anti-hæmagglutinin in mouse serum or with F.M.1 influenza serum. The s-antigen, that is the soluble antigen found in the original material, has similar serological properties to the g-antigen. Schäfer suggests that the g-antigen is located inside the particle, for no antibody is formed against the g-antigen when whole virus is inoculated into rabbits in which the virus does not multiply. In foot-and-mouth disease the small antigen liberated from the large particle would seem to be on the outside of the particle, since it is readily liberated. Damage by heat, probably not unlike ether treatment, leads to loss of specificity. It may be that some of the apparent identity of g and s-antigen in Schäfer's work is due to the damage to the g-antigen during its preparation. Certainly the comparison is closest

between the s-antigen of Schäfer, and the small complement-fixing component present in untreated virus suspensions in foot-and-mouth disease. There therefore seems to be a distinction between the small component derived from virus particles and those occurring naturally in the tissues. This is in spite of a marked similarity in the size of the material, and one would be inclined to consider that the dissimilarity in property was due to damage to the small antigen derived from the virus in splitting it from the virus, were it not for one observation in influenza by Ada (1957). He has differentiated between the disintegration soluble complement-fixing activity, that is the complement-fixing activity of the antigens of Schäfer's g-type, and those derived from the tissue, that is Schäfer's s-type. The former contains 5·3% of R.N.A. and the latter only 0·7% R.N.A.

The work of Kipps *et al.* (1957) ranges over a number of viruses. They describe the separation of soluble antigen from infective particle in poliomyelitis. The distribution of complement-fixing activity between supernatant and deposit of centrifuged suspensions of the virus in mouse brain was about 8–1 compared with 1–1 in our experience of foot-and-mouth disease. A further difference was that disintegration of the large particle in their case by drying, produced units of 10–12 mμ diameter with no release of soluble antigen. It would be interesting to have data on the specificity of the two particles in poliomyelitis since it has been shown that the specificity of the virus in complement-fixation tests is decreased by heating at 56° in a manner similar to that which has been associated with foot-and-mouth disease virus. If the South African workers are correct in their assumption that the large particle contributes little to the complement-fixing activity, the loss of specificity must be due to degradation of the small particle and not to disintegration of the large. In bluetongue and African horse sickness, the same workers have made studies of specificity of the components. These have been limited to the finding that the soluble antigen is relatively of low specificity. In general it has been the custom, as in the work of McIntosh (1956), to use the neutralization test as an index of specificity of the strains of the virus of African horse sickness and bluetongue. In foot-and-mouth disease, of course, neutralization tests and complement-fixation tests have given quantitatively similar data over a large number of subtype strains. The differentiation of type also gives a similar picture whether it is observed by complement fixation or serum neutralization.

The virus of influenza was the second in which soluble antigen was described. In the twenty years since that event the relationship between the active particles concerned has been built up into a structural hypothesis far beyond anything which is yet possible with the smaller viruses. Several points of difference stand out between influenza and the viruses we have been considering. The serological specificity of soluble antigen is type specific only, while the large particle is strain specific. This is in agreement with observations on foot-and-mouth disease, but, in addition, for foot-and-mouth disease there is the curious observation that although the small particles of two different types are difficult to distinguish, it is still possible to differentiate the small particles derived from two different strains of virus, just as effectively using strain specific antisera, as it is to differentiate the unfractionated virus. Sonic vibration removed some soluble antigen from the virus of influenza, but complete disintegration with loss of infectivity resulted in liberation of more soluble antigen. The implication is that, as with foot-and-mouth disease, there are small particles more or less closely bound to the surface of the large particle. These can be removed without loss of infectivity whilst in the deeper structure there is perhaps a reserve of soluble antigen which is liberated only on disintegration. There has been a tendency to regard the soluble antigen as the basic unit of virus multiplication. It is possible only to discuss this hypothesis in terms of influenza and some related viruses where there is some good supporting evidence. For other viruses it seems that a great deal more work is required to characterize the so-called soluble antigens, particularly in regard to their properties when they are obtained as a result of various treatments. It seems quite clear that the products which are obtained vary according to the severity of the process by which they are derived from the initial virus suspension. Further work is required also on the study of the physical properties of these materials. It seems clear that some at least of the so-called soluble antigens really consist of complex collections of particles of different size and different chemical composition. Work with the virus of vesicular stomatitis (Bradish, Brooksby and Dillon, 1956) indicated that there were at least four particles of different size in the viral suspensions, and it was almost impossible to delineate sharply the properties of the small particles, since they appeared to exist in variable proportions in different virus suspensions in a size range which it was difficult to separate in the centrifuge. It would not be surprising if this considerable diversity of composition and structure in the various viruses was related to a difference in the role which these small particles play in virus multiplication, structure and disintegration.

The diversity of characteristics of the virus seems to be a suitable place to finish. In

conclusion, it may be conjectured that, although it has not been possible yet to interrelate the two aspects of virology dealt with in this paper, the time is not too distant when each may contribute to the other. Structural changes on modification may yet be beyond our ability to detect, but this detection waits only on progress in this field.

## The Physiology of Memory

### PRESIDENT'S ADDRESS

By W. Ritchie Russell, C.B.E., M.D., D.Sc., F.R.C.P.

It is hard to realize that only 200 years ago the brain was still thought by our forefathers to consist of a concoction of spirits which might be pure and tranquil, or riotous and evil. It was no wonder that the highly complex human mind was considered to be a thing apart from this squashy organ. During the past 100 years, however, the astonishing complexity of the central nervous system (C.N.S.) has been slowly unfolded until its structural mysteries have become even harder to understand than say the so-called mental processes of our friends! This state of affairs has inevitably caused a revolution in man's attitude to his C.N.S., and indeed there seems to be little limit to what this structure might be capable of.

As examples of the changing concepts regarding the C.N.S., I propose to discuss briefly a few of the physiological processes which seem to be concerned with memory, but I should first point out that a certain amount of speculation is unavoidable in discussing a subject about which we know so little.

There seem to be two particularly important aspects of the development of C.N.S. patterns, to which I should like to refer. There is first the apparently fundamental tendency for nerve cells to repeat patterns of activity, so that all reactions have a strong tendency to form arrangements which are repeated whenever possible, and around which more elaborate responses are built. The tendency to repeat seems to be one of the most powerful features of all nervous system activity. The physiological basis for this is of great interest, and will be considered later.

The activity of the mature C.N.S. usually falls into well-worn patterns which have formed during the years of development. These furrows of habit become first, ruts to guide and then, chains which control our responses to a greater or lesser degree. These bonds of habit affect simple motor performances very strongly so that our very movements assume a unique character: thus the constancy of our handwriting must be a source of wonder and thankfulness to every banker. This capacity to repeat a previous response is clearly an essential part of the physiology of memory.

The second of these particularly important aspects is the capacity of all forms of animal life to encourage or discourage a response according to whether it appears to be advantageous or disadvantageous to the organism.

In the highly developed C.N.S. of man and mammals this system is probably thrown into action at birth by powerful afferents from the infant's viscera and orifices, especially the mouth, but this is soon elaborated into an ever more complex system in which fronto-hypothalamic mechanisms play an important part. This might be referred to as a *personal reaction* in which what we call *feeling* becomes a prominent feature. This reaction also shows a strong tendency to repetition, and is clearly concerned with the development of the individual feeling response to circumstances.

Although the studies of Freud and his followers have sometimes strayed from the path of reality, yet their insistence on the importance of the earliest infantile responses in relation to the development of future characteristics of the individual, is in accord with the background on which what I have called the personal response seems to develop. This appears to me to provide a powerful link between psychology and physiology, which are still somewhat artificially separated from each other. Certainly this personal reaction

to events itself forms patterns of response, or habits which seem to lay the foundations on which the individual's characteristics are formed.

From the point of view of memory itself, this personal response is of special importance as it helps to ensure that items which it considers to be advantageous are remembered, and of course, from the point of view of learning, the wish to learn is vital, and presumably represents the personal reaction to what is unknown.

Here then are two striking features of C.N.S. activity—the urge to repeat and the capacity to facilitate what is advantageous—and it is especially with the first of these that we are concerned in studying memory.

Ever since anatomists (including Ramon y Cajal) discovered that the C.N.S. is built up of neurones, it has been realized that much must depend on the properties of these units, and the manner by which they form synaptic connexions with each other.

It is therefore of great importance from the point of view of our subject that neurophysiologists have, in recent years, demonstrated that transmission from one cell to another is greatly augmented if there has been preceding activity across this connexion. This effect has been shown by experiment to operate exclusively in the presynaptic apparatus (Eccles, 1957; Granit, 1955). This is evidence regarding a neuronal mechanism which can be correlated with the tendency to repeat which permeates all levels of C.N.S. activity.

## Physiological Mechanism of the Ability to Repeat

In attempting to provide a working hypothesis for the most primitive type of memory—the simple repetition of a reaction—we must appreciate that most cells of the C.N.S. are in a state of constant, if somewhat random, activity in which they discharge spontaneously day and night, often at a high rate along the processes which communicate with other nerve cells (Young, 1946). The afferent stimuli which lead to reaction or action, are not therefore thrown into a mechanism which is idly waiting for something to do, but into one which is already busily occupied. It is equally evident, however, that this complicated neuronal activity is extremely sensitive to outside (afferent) influences. Apparently the neuronal pool can be alerted to make responses which take priority over spontaneous activity, but a trained and attentive C.N.S. will direct new arrivals into well-established channels, so that if a certain response has in the past followed a given experience, there is every likelihood that this response will be repeated in the future to the same stimulus, until it acquires a remarkable degree of constancy and automaticity.

Even the simplest C.N.S. response involves a vast number of repetitions in the physiological sense; thus the cells involved may perhaps discharge at the rate of 500 per second for several seconds during the height of the response, and may then settle down to relatively slow spontaneous 40–50 per second which causes no overt effect and yet may play a part in preserving the pattern of response.

## Simple Learning Processes

The development of constancy in this response constitutes a learning process and in many instances a response seems to be learned quite quickly. Apart from brief interruptions, the neurones concerned continue their spontaneous discharges, and it seems natural to consider that *these spontaneous discharges tend to be directed into the paths opened up by the learned response.* Having learned to walk or cycle one never forgets, not because some pattern is hidden away in a mysterious memory centre, but because the spontaneous activity of the neurones concerned maintains and indeed strengthens the once-established pattern of the response. This mechanism is so remarkably effective that the task once learned may be executed better after an interval of apparent neglect, and the suggestion made is that the C.N.S. maintains what is learned by spontaneous discharges of the cells which are "exercising" as it were, through the neuronal pattern established when the skill was first acquired (Russell, 1948).

In other words the establishment of the original pattern for the response also established the direction in which the spontaneously occurring activity would tend to flow, and this in its turn would strengthen itself and thus maintain and consolidate the capacity of the organism to repeat, retain and strengthen the skill.

In this sense therefore and unbeknown to the individual, the C.N.S. practises its learned skills and other memories throughout life.

This raises interesting possibilities for there may well be circumstances in which the unconscious activity of the C.N.S. provides a more effective form of training than does actual practice; and, of course, it is intriguing to speculate on the part which this mechanism may

olay in assisting the mental clarification which often results from putting aside a complicated problem from one's conscious thought for a few days or hours.

Here, however, I am jumping to the conclusion that the memory of a physical task and of a so-called mental problem are basically dependent on the same physiological mechanisms.

### Structural Changes at Synapses

The physiological mechanism whereby an active synapse becomes facilitated for future use is not fully understood, but there is some evidence to suggest that physical changes may play a part. Thus the synaptic knobs on the surface of anterior horn cells may, in response to great activity, get larger (Eccles, 1953), and recent work raises some interesting possibilities about a somewhat similar process in the inter-fibre synapses of the cortex. For long there has been something of a mystery about inter-fibre transmission in the cortex but studies described by Bok (1956) suggest a plausible explanation. He has found that 90% of the cerebral cortex consists of spaces which separate nerve cells, glial cells and blood vessels. In this space an immense number of nerve fibres cross each other in various directions, and this fibre density remains much the same in different layers of the cortex, and indeed as between man and animals. The distance which separates crossing nerve fibres is also remarkably constant, and this separation of one fibre from another is apparently maintained by a foam-like structure of spheres whose diameter is about 5$\mu$. It is suggested therefore that fibre synapses depend partly just on the distance which separates fibres from each other. In other words close crossings are facilitated synapses.

A further clue to this is probably provided by a study of the spikes (gemmuli) which appear on the dendrites of cortical pyramidal-type cells. Bok has demonstrated that the gemmuli on a dendrite are, on the whole, separated from each other by a regular distance (2·5$\mu$). This corresponds to the distance apart of the points where crossing fibres would come in close contact with the dendrites on the above arrangement of foam particles. It seems therefore that every spike on the dendrites may become a close-crossing synapse. Further the development of the gemmuli greatly enhances the effectiveness of the close-crossing synapse by further approximating the crossing fibres. Indeed this increase in size of the fibre at the point of crossing almost (and perhaps entirely) eliminates the space between the crossing fibres. In this simple way the effectiveness of the synapse receives the maximum enhancement.

The development of these gemmuli is presumably a physical change which results from the activity of the synapses concerned, and plays an important part in enhancing their activity. Tremendous multiplication of these occurs during first two years of life. The crossing at the gemmuli suggests a very firmly-established type of close-crossing synapse, but it may be assumed that simpler mechanisms of enhancement occur without the formation of so much physical change.

In any case the available physiological knowledge suggests that patterns of behaviour depend on the establishment of functional changes at the synapses and not in the cell body. When we laboriously learn to walk we establish a pattern of reaction which probably differs only in the degree of complexity from the higher forms of memory. This conception is important for it suggests that memory, far from depending on passive changes in nerve cells, is a very active process, and becomes lost only when the neurones concerned cease to discharge along the pathways once facilitated. The student of the brain must often be astounded by the complexity of function involved in the simplest mental process, and yet the complexity of the mechanisms involved in voluntary movement is equally astonishing. It is safe to say that if we could understand fully the mechanisms involved in learning the patterns of voluntary motor activity we would be more than half-way towards understanding the physiology of thought processes.

There has sometimes been a tendency to look for some special area of the brain into which all memories could be filed, but this has always seemed to me to be a highly improbable conception. Thus the memory of a physical skill must surely be contained in all parts and levels of the C.N.S. which influence the performance of the skill. Memory of a skill and capacity to repeat it are to some extent one and the same, and the same principle should apply to the higher forms of memory.

Another quality of C.N.S. activity is its capacity to effect a series of responses in a certain order and sequence, and this is a very constant feature of learned responses. From the physiological point of view various phenomena have been demonstrated which introduce delays from one cell to another, but apart from this, the time and sequence patterns of these reactions are little understood. In general, however, there is a striking tendency in all C.N.S. activity for one response to be followed by another, and indeed many motor

performances of skill depend almost entirely on reactions which can only occur as a sequence to the first action.

There is also the capacity to co-ordinate one motor memory with another: thus a bandsman remembers both how to walk and how at the same time to play the drum. Presumably our capacity to associate one memory with another at a high level differs again only in complexity with such sensorimotor reactions.

A poem or a piece of music is most easily remembered as a sequence which follows the beginning, and in the highest forms of memory, those with exceptional power in this direction depend largely on a vast capacity of associating memories with each other this seems to represent a vastly complex type of the simpler ability for one motor reaction to be followed by another.

The recognition of the familiar is an important aspect of memory. A familiar or unfamiliar sight must project in the same pattern on the visual cortex. Most of those patterns are promptly extinguished, but if some attention is aroused, then the familiar is quickly recognized, presumably because the pattern is entering facilitated circuits. Familiar patterns often stimulate a personal feeling of contentment. On the other hand a highly unfamiliar pattern of sound or sight often acts as a strongly alerting reaction with the personal response of fear. These interesting facets of memory are of special interest, as feeling responses to the familiar and unfamiliar may be abolished in animals by certain temporal lobe excisions.

## Phantom Limbs

The study of phantom limbs in amputees provides some interesting examples of sensorimotor memory. It is natural that the brain should interpret sensations from the cut nerves as originating in the missing limb. The brain has been trained for many years to interpret these sensations in this way. But if a child should lose a limb in the early months of life, no phantom will develop as the opposite parietal lobe has not yet developed a strong association with the limb.

In many amputees the phantom sensations disappear after a few months. In some, however, after an interval of perhaps twenty years, a painful condition develops in the stump, and once again severe pains are experienced in the phantom. This is a remarkable example of the preservation of an entirely neglected sensorimotor memory. Even more remarkable is that the phantom pain may revive memory of a pain which was felt severely before the limb was amputated (Russell and Spalding, 1950).

In this connexion it is of interest to note that wounds of the parietal lobe of the brain may abolish appreciation of the position of contralateral limbs in relation to the rest of the body (Brain, 1950)—the so-called loss of body image; and in contrast an epileptic aura originating in the parietal lobe may occasionally be a strong phantom sensation in an opposite limb—a forceful distortion of the body image mechanism (Russell, 1951).

## The Hippocampal System

There is plenty of evidence to indicate that the hippocampal system is very much involved in this mechanism of memory and recognition of the familiar. Removal of the hippocampus and anterior temporal lobes on both sides causes a remarkable state as Scoville and Milner report (1957). They found that in patients so treated the incidents of daily life were forgotten as quickly as they occurred. Yet details of childhood were well remembered. A somewhat similar result follows disease of the region of the mammillary bodies as in Korsakoff's psychosis, and these bodies form an essential link in the hippocampal system.

Of special interest in this connexion are the temporal-lobe fits which cause an intense sense of familiarity for in this type of focal fit all that is happening seems as if it had happened in the same way before. No other part of the brain stimulates a sense of intense familiarity or *déjà vu* sensation and it seems likely that the hippocampus is concerned. The focal epileptic fit often caricatures the function of the part of the brain affected so that the occurrence of such fits from the temporal lobe confirms the importance of this region for the physiological reaction which is needed to facilitate neuronal patterns in such a way as to enable an event to be remembered, and to become familiar.

In Korsakoff's syndrome also there is a remarkable dissociation between remote memory and remembering of current events. For it seems as though these remote memories were learned originally with the assistance of a mechanism now out of order, and new learning becomes impossible, though the earlier results are still available. The mechanism that is now out of order was probably the one used to establish originally what is preserved.

This separation of function is also seen in many other states of disordered brain function such, for example, as occur during recovery from concussion. It seems that the mechanism of adding to memories—the recording of events—is more complex and relatively vulnerable, while what was added to memory before the disorder of the mechanism remains relatively secure.

In Korsakoff's syndrome there is plenty of evidence to indicate that an important link in the hippocampal system is broken, for the corpora mammillaria show gross changes and their relations with the hippocampus are so close that their inactivation might be expected to put the system out of action.

It is not unduly fanciful, therefore, to consider that the hippocampus plays an important part in both memory and learning processes. It certainly has free connexions with all parts of the cortex, and such a major contribution to thought and behaviour would give it a role well worthy of its great development in man and animals. Yet, although concerned with learning, it probably plays little part in actually storing what has been learned. Its action on the cortical mechanism concerned with visual memory, for example, must be a boosting, feed-back or re-playing mechanism. And, in addition, it might contribute to the essential stimulation of associated ideas and feelings which are so important in consolidating memories.

It is of great interest to study those parts of the brain from which formed visual hallucinations may occur as part of an epileptic process. Dr. Whitty and I (Russell and Whitty, 1955) found that these might occur not only in temporal lobe injuries but also in parieto-occipital lesions. This suggests that both sites are intimately concerned with visual memory; the parieto-occipital region being the region where the main pattern of facilitated circuits lies, and the temporal lobe being concerned perhaps through the hippocampal system in boosting these mechanisms.

These posterior lesions may cause hallucinations of remembered scenes as described by Robinson and Watt (1947), and from wounds further forward in the parietal lobe there may be, as already mentioned, phantom sensations (Russell, 1951) which represent a distortion of the memory of the position of the contralateral limbs in relation to the body image. The disappearance of visual memory and of dreaming (Humphrey and Zangwill, 1951) have been reported in destructive lesions of this part of the brain.

Study of the effects of head injury or senile changes on memory also demonstrate the special vulnerability of recent memories, and indeed it seems that many memories are strengthened with the passage of time regardless of their importance to the individual. This is what one would expect if memory depends on synaptic facilitation of neuronal circuits, which continue to strengthen themselves whether we are interested in them or not.

## Hallucinations

Hallucinations provide an interesting study of a disordered memory mechanism. Visual hallucinations are generally of objects which are recognized by virtue of previously acquired knowledge. Thus in delirium tremens the victim is in no doubt as to the type of animals he sees for their appearances are quite familiar to him.

Many individuals with a strong visual sense can develop a special capacity to see things in their mind's eye. This is a simple physiological phenomenon, which may result in artistic productions. Some forms of modern art seem to depend on a cultivated capacity for hallucinatory phenomena to occur in relation to certain feelings. The idea, however, that these haphazard visual images are worth reproducing as works of art seems to me to be based on a misconception of their physiological significance. The artist seems to think that these phenomena are emerging from some unique storehouse of his personal genius, but, on the contrary, the available evidence suggests more that they represent a confused glimpse of fragmentary repetitions of previous thought or reactions.

Hallucinations during illness are likely to be based on remote memories around which there were at one time strong emotional feelings. Thus a woman with delirium tremens may scream with terror at pink mice on the walls, and yet it may have been many years previously that she last experienced an emotional reaction of fear in relation to mice.

A middle-aged doctor while experiencing an infective disease causing an encephalopathy developed some hallucinations which were, in general, of featureless buildings, but somewhat to his surprise, these hallucinations included an illustration from an anatomy textbook which had interested him greatly when he was a young medical student many years previously.

Of special interest are hallucinations of self (Dewhurst and Pearson, 1955), as they tend to be of head and shoulders as would often have been seen in a mirror, and no doubt this

appearance has also at one time, perhaps many years previously, aroused an undue amount of interest in the person concerned.

The various visual and auditory memories with their associated emotional responses are contained chiefly in different areas of the cerebral hemispheres, but during hallucinosis the stimulus to uncontrolled activity seems to come from some central system which plays back excessively to the regions such as the parieto-occipital region which is so much concerned with visual memory. The actual hallucinations which appear must depend on many chance factors just as occurs in dreams which, no doubt, make use of a similar mechanism. Indeed hallucinations and dreams are similar in many respects.

The traumatic amnesias are of great interest in relation to our subject (Russell and Nathan, 1946). It is now generally agreed that the concussive effect of a closed head injury is a direct physical disturbance of neuronal function, which leads to a paralysis of brain function.

The gradual recovery of mental processes after head injury provides a vivid picture of the return of first, the less complex, and last, the more complex mechanisms. In this connexion it is informative to realize that current events are not remembered until the recovery of brain function is more or less complete.

During recovery of consciousness it is of special interest to study the commonly occurring phenomenon of shrinkage in the retrograde amnesia. This is best observed in severe cases with slow recovery over a period of several days or weeks. During such recovery recent memories may be so severely lost that the patient thinks himself to be some years younger, and expects the environment and date to be appropriate for that age. Further, if the injury is of such severity as to cause some permanent loss of things previously learned, then this loss is most likely to affect recently acquired knowledge or skills.

Thus in all traumatic or disease processes of the brain there is evidence that recently acquired memories are most vulnerable, while remote memories are often remarkably resistant to disease or trauma. This is therefore a fundamental feature of cerebral dissolution, and can, I think, be explained on the basis put forward that memories depend on synaptic facilitations which strengthen automatically as time passes. Early childhood memories may be relatively indelible for the further reason that the physical changes consequent on prolonged facilitation at a synapse no doubt develop most readily in the child's brain.

The occurrence almost invariably of a short period of retrograde amnesia after recovering from concussion is of course of very special importance, for it clearly indicates that the establishment of a memory, even of the most vivid and emotionally tinged type, requires a period of one or two seconds of normal brain activity, if it is to survive the paralysing effect of concussion. This seems to be a very short time but one second is quite a long time from the neurophysiological point of view.

Of special interest are the occasional visual hallucinations soon after recovering consciousness after head injury. These may be concerned with dramatic events which fall within the period of retrograde amnesia (Russell, 1935; Russell and Nathan, 1946). These visions are only half memories and are soon lost. There is no associated feeling in regard to them, and this can presumably be correlated with their not having been played on by hippocampal and emotional mechanisms.

We might here almost guess that the hippocampal system has to play back to the parieto-occipital region for a period of seconds before even a vivid visual experience can be established as a faint memory. If the cells concerned discharge at the rate of up to 500 per second one gets a rough estimate of how long this effect requires to come through.

It is, of course, even more remarkable that this mechanism of remembering is so efficient that many victims of moderately severe head injuries remember clearly the events which occurred say 10 seconds before the injury. This suggests that the neuronal activity even during the period of traumatic confusion continues to strengthen its memories through its spontaneous activity.

The time factor is only one of many which are concerned with memory. For example, the factor of attention seems to be perhaps the most important of all, for afferents pouring in from the special senses seem to be extinguished automatically, unless they arouse what Pavlov called the "What is it?" reaction.

Further the gradual strengthening of a memory with the passage of time depends on its remaining relatively isolated, and not becoming confused by a large number of closely similar memories, as I have previously pointed out (Russell, 1948). An experience is not so easily recalled when it ceases to be unique, but becomes confused by scores of very similar memories.

In conclusion, I can only draw a somewhat terrifying picture of thousands of millions of nerve cells all discharging throughout life at high speed, by day and by night to maintain the synaptic patterns on which our memories depend. The very thought of such a mechanism must fill us with a feeling of incredulity. Certainly it makes one tired to think of, but then mental tiredness is itself a remarkable phenomenon.

If our memories are, in fact, facilitated neuronal circuits which never rest, how can we prevent them from constantly disturbing our lives? Thus if the memory of how to swim involves circuits which never rest, why are we not constantly waving our arms and legs around in response to this constant activity?

The answer may lie in a study of what happens to nearly all impulses reaching the nervous system, for it has become quite evident that only a minute fraction of say visual afferents from the retina are "seen" at all. It seems that nearly all afferents to the C.N.S. are immediately extinguished by a process of inhibition. How can this come about? The neurophysiologist will naturally think of the recently described recurrent twigs from the axons of pyramidal cells which have a powerful influence on an inhibitory system connected with the cells described by Renshaw (1946). It is thus quite possible that every pyramidal type of cell has its own cut-out system. In this way it becomes conceivable that our memory neuronal patterns can remain constantly active without reaching what we call consciousness.

What enables us to think of one of our memories or to remember something we see or hear, seems to depend on some general alerting process, and we might here even use the term centrencephalic system as visualized by Penfield.

A friend of mine, a research worker of exceptional originality, told me that if a ticking clock stopped while he was engaged in some mental activity unrelated to the clock, he realized that something had happened and his first memory was of the clock ticking before it had stopped, and he estimated that he would remember about 5 seconds of ticking before it ceased.

Thus it seems that the change from ticking to non-ticking alerted the hearing side of the brain, and that this enabled the memory of recent ticks to be recaptured before they were extinguished like the memory of all other ticks. It is well known that those in charge of running machinery of any kind are alerted by any change in the running sounds.

Also if one suddenly starts listening to what someone is saying, it may be possible to recapture the word or two before alerting began, usually not enough to avoid getting into trouble for not listening to what is being said.

In any case it seems evident that we rely on nearly all the afferents arriving at the C.N.S. being promptly extinguished, and one might even guess that a disturbance of this balance might play a part in the ætiology of traumatic epilepsy.

It must be obvious from this brief address that there are more unsolved than solved problems. Yet from time to time we must try to take another step forward towards unravelling the mysteries of cerebral mechanisms.

## The Ageing Eye

### PRESIDENT'S ADDRESS

By J. R. WHEELER, F.R.C.S.Ed.
*Belfast*

THE last fifty years have seen tremendous advances in all branches of science, and in the science of medicine these advances might be termed spectacular. Insulin, liver therapy, sulphonamides, antibiotics, corticosteroids and hypotensive drugs, to mention but a few, all help to prolong the lives of the population, so one finds a much larger proportion of people living beyond the Biblical span of three score years and ten.

It is interesting to observe the estimated population of persons over 65 years of age during the next forty years as shown in the Registrar-General's returns. One notices that a very considerable increase of longevity is predicted, and that in the 85 and over group the number of persons alive will be more than double what it is to-day.

ENGLAND AND WALES

Table Population, Projections from mid-1955 by Sex and Age. Prepared by Government Actuary's Department in consultation with the General Register Office

*Figures in Thousands*

| *Age* | 1955 | 1975 | 1995 |
|---|---|---|---|
| 65 | M. 785 | M. 1,154 | M. 1,066 |
| | F. 1,082 | F. 1,396 | F. 1,255 |
| | 1,867 | 2,550 | 2,321 |
| 75 | M. 385 | M. 484 | M. 572 |
| | F. 617 | F. 828 | F. 874 |
| | 1,002 | 1,312 | 1,446 |
| 85 and over | M. 78 | M. 97 | M. 159 |
| | F. 167 | F. 270 | F. 389 |
| | 245 | 367 | 548 |

Man is probably at the peak point of physical fitness in the mid-twenty period—it is at this age that one will find the majority of Olympic sprint champions. More maturity, however, is required for long distance races which put a long-sustained strain on the cardiovascular system.

Perhaps the first positive sign we get that the process of ageing is upon us is the onset of presbyopia. Then the onset of the post-reproductive age period may bring with it some degree of rheumatism or arthritis.

Most degenerative conditions are secondary to a less efficient blood supply through less elastic arteries—it would seem that tissues have a time scale beyond which either no replacement takes place or the replacement takes place with increased lack of efficiency. Then there is a group of conditions with the age of onset under genetic control—severe vascular hypertension, myocardial infarction, &c. Finally the older age groups have probably been exposed to a larger series of traumatic insults from injury or disease and so are more liable to suffer from their cumulative experiences.

To try to find out the true position of the ageing eye, I have surveyed three groups of persons who have passed the usual, if arbitrary, retiring age of 65 years.

*First:* The registered blind persons in Northern Ireland over 65 years of age.
*Second:* Over 250 inmates of a geriatric unit.
*Third:* 138 inmates of an old people's home.

## Registered Blind Persons

Before reviewing the data contained in the blind registration certificates obtained from the Ministry of Health in Northern Ireland there are three points to which I would like to draw attention:

(1) All patients were examined by an ophthalmic specialist.

(2) The official definition of a blind person under the Act is one who is unable to perform any work for which eyesight is essential. This is a good practical definition, but obviously somewhat loose and open to slight variations. One finds in practice that perhaps 15% of these certified blind persons are able to look after themselves and get about in their own known surroundings.

(3) To qualify for a blind pension one's income must be below a certain figure. The total list of registered blind persons shows that less than 50% draw a pension.

### Causes of Blindness

(in persons of 65 years and over)

| | % | | % |
|---|---|---|---|
| Cataract .. .. | 31·43 | Corneal .. .. | 5·48 |
| Glaucoma .. .. | 19·15 | Old trachoma .. | 1·28 |
| Myopia .. .. | 10·51 | Optic atrophy .. | 3·60 |
| Macular lesions .. | 6·76 | Retinal detachment | 1·28 |
| Vascular .. .. | 4·74 | Congenital .. | 1·26 |
| Choroidal .. | 3·88 | Disease of C.N.S. .. | 0·86 |
| Iritis and cyclitis .. | 6·62 | Trauma .. .. | 0·43 |
| | | Unclassified .. | 2·72 |
| | 83·09% | | 16·91% |

Reviewing the data available from the Northern Ireland Ministry of Health I find that out of a population of 1,394,000 people 2,600 were certified as blind, or one person in every 536. The data from England and Wales for the same period shows that one person in every 485 is certified as blind.

Of the 2,600 blind in Northern Ireland 65% are 65 years of age and over (the age group being examined). The number of cases of cataract is 31%, glaucoma 19%, and a group which might be termed chorio-retinal irrigation lesions, 15%. The other main lesions are the end-results of inflammatory reactions of the structures forming the anterior segment of the eye, which, when one includes old trachoma cases, stand at 13%. These lesions, plus the cases of high myopia with fundus defects, form the major causes of blindness in the 65 and over age group.

Examination of the blind certificates shows that the great majority of the cataract cases have not even sought medical treatment. Why this state of affairs?—after all, the results of surgery to-day are very good. Gone are the days when one had to wait until the cataract was mature before operating. I tell my students that when the patient's vision is such that he is unable to carry on his work, then it is the surgeon's duty to operate. Unilateral cataracts should be operated upon at the patient's convenience as it gives an increased visual field and also a good "reserve" eye. With advancing years the patient's general health cannot be expected to be perfect—if, however, it is reasonably good, operation is worth trying. There is so much to be gained and so little to lose. Many good results are obtained in patients who are far from 100% fit. In 1953 I read a paper at the Oxford Ophthalmological Congress analysing 114 consecutive cases of cataract I had operated upon. 67% got 6/12 or better vision, while in a further 23% of cases vision was 6/60 or better. Could not this good prognosis which modern surgery offers to those affected with advancing lens opacities be made more widely known, so that they might seek our aid at an earlier date?

An analysis of figures shows that townspeople were the worst offenders in not seeking advice—probably individuals with limited or impoverished life experience, especially as regards hospitals—they develop an anxiety neurosis and have a reduced capacity to deal with events. Old people adjust poorly to changes in environment and readily become emotionally upset with new and different situations, especially separation from their families.

### Senile Changes

It has been suggested that senile cataracts may be part of a generalized degenerative process, and, if this is so, persons with senile cataracts would be more predisposed to structural brain changes than other individuals of the same age group. The probable reason for this suggestion is that occasionally following cataract operation the patient becomes mentally upset. This may vary in degree from acute mania to a mild degree of confusion or disorientation.

The first case report of this in English is in the *Medical Times and Gazette* in 1854. An interesting account is given of a man of 65 years with bilateral cataract—"so great was his fright and agitation that he could not be induced to keep quiet enough to allow his eyes to be opened sufficiently for the operation. The procedure had to be postponed for twenty-four hours so that chloroform could be used. On the first post-operative day delirium set in and continued with violence for five days, during which time the head was tossed about in all imaginable positions". The account says he recovered, and three weeks after operation he saw as well as possible after removal of the lens.

Linn (and others) reporting from departments of Psychiatry, Neurology and Ophthalmology of Mount Sinai Hospital, New York City, on 21 unselected patients with bilateral senile cataracts, state that following cataract extraction 62% of cases showed severely disturbed reactions, while 95% showed some alteration in behaviour. Only 3 cases in the series had a normal EEG and a negative amytal test. These figures are obviously far too high for our country but one must remember that they were dealing with a very mixed population, with language difficulties and with bilateral cataracts. This would bear out the general opinion that it was the structural brain changes present prior to the operation that predisposed these patients to the post-operative psychiatric disorders.

Could it be that these senile mental degenerative changes prevent so many patients, with cataract, from coming to hospital to seek advice and treatment? The older the patient the more liable are these brain changes to be present. The longer the darkness and loneliness period, the more liable are these patients to become introspective, so that delusions and anxiety states arise.

Ophthalmic surgeons should try to get these cases to hospital at as early an age as possible and not give them an opportunity to weave a psychosis out of their phobias of becoming blind, lonely and a burden on their families. Now with the Welfare State one might hope that general practitioners, ophthalmic opticians, health visitors, &c., might persuade these people to come to us in hospital as soon as a cataract is suspected—then we could assess their case and tell them when the opportune time for operation might be. If ready for operation make the waiting time as short as possible; if not ready, tell the patient to return on a certain definite date for re-examination. Try and gain their confidence, and assure them that everything possible will be done to restore their vision.

### Glaucoma

Turning to simple glaucoma—that slow but remorselessly progressive lesion which accounts for almost 20% of blindness in the over 65 age group: ten years ago a very cultured Scot (aged 56) came into my consulting room and told me he had got glaucoma, saying that both his father and eldest brother went blind from glaucoma, and both were operated on by a leading Scottish surgeon. He said it appeared that his family reacted badly to operation and so he did not wish to have an operation. He asked me to give him some warning if he was going blind so that he might buy a house with a little garden where he would be able to find his way about and look after his plants. For the last ten years he has faithfully carried out the recognized conservative treatment for glaucoma. When first examined the diagnosis was definite but field contractions slight—ten years later one eye is blind, and the other has 6/6 vision but the field is contracted to within 10 degrees of the fixation spot.

Perhaps this case may show about how long a conscientious patient's sight may survive under conservative measures. I feel, however, that operations on very advanced cases with markedly contracted field have a poor prognosis and give the operation a bad name.

The blind registration certificates show how few of these glaucoma cases had had any operative treatment, or indeed any treatment. If we could get these cases early our operation results would show a much higher percentage of success.

### Sympathetic Ophthalmia

One must remember that to open the eye carries with it a risk of a resulting sympathetic ophthalmia. Sorsby points out that half of the sympathetic ophthalmia cases causing blindness result from cataract surgery, while 1/6 of this number followed operation for glaucoma. To-day, with the advent of the corticosteroids, antibiotics and sulphonamides

we have a line of treatment which, if pursued energetically, should prevent this dreaded condition materializing. These drugs can have an almost miraculous effect in ordinary cases of iridocyclitis and keratitis, but of course one cannot expect them to undo serious existing established damage. With their early and judicious use, however, blindness resulting from inflammatory lesions of the anterior segment of the eye might possibly be reduced from 13% to almost nil.

### A Geriatric Unit: A Survey of the Eyes of 277 Persons of Age 65 and Over

In this unit cases are classified as follows:

A. Fit, but admitted for social reasons.
B. Frail, ambulant—can get about in hospital but not fit for home.
C. Sick (1) Acute—will eventually recover sufficiently to go home.
(2) Chronic—will not recover sufficiently to go home.
D. Psychiatric—patients admitted because of mental rather than physical inability to look after themselves.
E. Special Groups—e.g. Huntington's chorea, &c.

This group of cases of elderly, frail and infirm persons produced an entirely different ocular pathological picture from what I had expected to find. There are less than 12% with some opacification of the mediæ, and only two cases of glaucoma were found.

The reason for this is probably that people who are simply blind require little or no nursing, and their relatives are encouraged to keep them at home by receiving extra National Assistance. National Assistance is 40/– in the ordinary way, but in the case of a certified blind adult it rises to 60/–, subject to a means test.

The Medical Conditions of a Cross-section of 277 Patients of Age 65 Years and Over

| | | % |
|---|---|---|
| 117 | Cerebrovascular accidents .. .. .. .. .. | 42 |
| 44 | Other cardiovascular lesions .. .. .. .. .. | 16 |
| 61 | Cripples—Rheumatoid arthritis, ununited fractures, &c. .. | 22 |
| 25 | "Social reason" cases .. .. .. .. .. | 9 |
| 30 | Other cases—psychiatric, lesions of C.N.S., neoplasms, &c. | 11 |
| | | 100 |

Analysing the medical condition of my cross-section of patients in this unit I find that 42% of the total had a cerebrovascular lesion, while a further 16% had some other cardiovascular lesion—these two giving a total of 58% of the whole. Of the rest 22% were cripples from rheumatoid arthritis, ununited fractures, &c., 11% included psychiatric cases, lesions of C.N.S., neoplasms, &c., while 9% were inmates for social reasons.

### Cerebrovascular Accidents at Age 65 or Over

The eyes of all this group were examined under a mydriatic, and I want to report specially on the 117 cases that had a cerebrovascular accident.

The Eye Condition of 117 Cases with a Cerebrovascular Accident of Age 65 and Over

| | Age 65/74 (43 cases) | Age 75/84 (63 cases) | Age 85 and over (11 cases) |
|---|---|---|---|
| Normal .. .. | 16 | 16 | 3 |
| Sclerosis retinal vessels | 15 | 23 | 3 |
| Retinopathy .. .. | 9 | 14 | 2 |
| Opacities of mediæ .. | 3 | 8 | 3 |
| Glaucoma .. .. | 0 | 2 | 0 |

Note: Sclerosis of retinal vessels may be slight to extreme but there is no retinopathy. Retinopathy (including optic atrophy) nearly always discrete degenerative type, rarely hæmorrhages or exudates. Opacities of mediæ nearly always lenticular—rarely corneal or vitreous.

It was especially interesting to find so relatively little opacification of the mediæ, and this made examination of the fundi an easy task. One could assess how the function of retinal irrigation was being carried on, and also the state of the retinal vessels.

### High Blood Pressure

High blood pressure has almost no known cause. It is well known that there are a group of individuals who constitutionally and genetically are predisposed to develop blood pressure well above the average with increasing age. There is, however, no arbitrary means of separating hypertensive individuals from normotensive ones.

A blood pressure of 155/90 may be taken as the highest normal figure, but with advancing years and less recoil in the great vessels the systolic pressure may be expected to rise. It is the diastolic pressure, however, which is all-important—it represents the resistance which ventricular contraction must overcome to open aortic valves and approximates more closely to the mean blood pressure. The prognosis in hypertension seemingly depends mainly on diastolic pressure. A diastolic above the critical level of say 140 mm. carries a grave prognosis.

Leathem states that a high diastolic pressure gives cardiac enlargement and retinal changes in 89% of cases, while a high systolic with normal diastolic gives retinal changes in only 50% of cases.

In examining the retinal vessels for evidence of vascular sclerosis the changes one regards as peculiar to this state are:

(1) Irregular lumen.
(2) Arteries narrower than veins.
(3) Opacification of arterial wall at arteriovenous crossings causing "nipping" of vein.
(4) Pallor of arteriolar blood column or broad or exaggerated reflexes from the vessels.

Blood Pressure in mm. of Hg of 117 Cases with a Cerebrovascular Accident of Age 65 and Over

| Age | Systolic | | | Diastolic | |
|---|---|---|---|---|---|
| | Highest | Lowest | | Highest | Lowest |
| 65/74 (43 cases) | 240 | 110 | | 120 | 60 |
| | Average: | Systolic | 176 | | |
| | | Diastolic | 97 | | |
| 75/84 (63 cases) | 240 | 110 | | 130 | 70 |
| | Average: | Systolic | 193 | | |
| | | Diastolic | 98 | | |
| 85 and over (11 cases) | 210 | 140 | | 120 | 70 |
| | Average: | Systolic | 165 | | |
| | | Diastolic | 93 | | |

Of the 117 cases under review 43 were in the first age group, 65–74. About one-third of these cases showed normal fundi, while a further one-third had definite vascular sclerosis but no retinopathy. The estimation of vision in these cases is difficult as many are bedridden, mentally confused, &c., but about 50% of "no retinopathy" cases took quite an interest and were able to read.

The other two groups (75–84 and 85 and over) showed a somewhat similar state of the fundi, but the general cerebral condition was definitely worse in the oldest age group. The review of the blood pressure in this series of cases is interesting. The relatively good condition of the fundi is in keeping with the low average diastolic pressures in all these groups—actually only 2 cases had a figure over 120. On the systolic side an average of 180 for these age groups is also on the low side. Perhaps the sheltered life and good care they receive has some effect on these figures. However, on the basis of these figures one might add to Leathem's statement about retinal changes with high diastolic and systolic pressures, and say that with reasonably normal diastolic and systolic pressure in these older age groups only 25% show any retinopathy. Admittedly another 35% showed evidence of retinal vascular sclerosis. Lyle points out that these arteriosclerotic vascular diseases usually occur above the age of 60 and the retinopathy, if present, is of a dry, hard or discrete type. On the other hand the hypertensive arteriolopathy occurs in the 40–60 period and is associated with hæmorrhages, œdema and soft exudates.

The discrete use of the hypertensive drugs, anticoagulants, sedatives, diet, &c., will no doubt bring these two groups closer together, but it would seem that the basic underlying aetiology is different. Possibly very few of the hypertensive arteriolopathy group reach the age of 65, and this would seem to be confirmed by my geriatric survey.

### The Healthy Aged Person in an Old People's Home

To turn from the frail and infirm old people to a group of persons who begin their lives in an old people's home in a relatively fit condition:

Clifton House was founded over one hundred years ago and is run by the Belfast Charitable Society. The persons admitted must be 65 years of age or over and must pass a cursory medical examination as to their relative fitness. Social considerations are the main criteria for admission, but no persons are admitted who are likely to become a nursing liability in the immediate future. Once admitted, however, they are kept until they die. Three inmates are centenarians, the oldest being a man aged 104 who can still read small print and is mentally and physically fit. He goes for a one mile walk into the city centre daily. A second man, at the age of 102, can still see to get around and look after himself, but the third member (a woman) has very poor sight.

Old People's Home

| | Age 65/74 | Age 75/84 | Age 85 and over |
|---|---|---|---|
| No. of cases .. .. | 15 | 81 | 42 |
| Can read with glasses .. | 14 | 74 | 36 |
| Cause of defective vision | 1 glaucoma (also senile) | 1 fundus degeneration<br>6 lens opacities<br>6 senile but 3 can read | 1 fundus degeneration<br>5 lens opacities<br>9 senile but 7 can read |

(Senile means senile mental degenerative changes.)

The overall picture of the 138 persons in the home shows that no less than 90% can still read with glasses. Of the 14 cases who are unable to read there was 1 case of glaucoma, 2 with clear mediæ but obvious arteriosclerotic fundus defects, while the remainder are due to varying degrees of lens opacities. Only 3 cases of cataract have had an operation but more than 50%, while unable to read, are able to get about, feed themselves, &c.

Of 16 cases (12%) with obvious senile mental degenerative changes like confusion, disorientation, &c., no less than 10 can still read and have no gross eye lesion. Thus it would appear that in these well-cared-for old folk the structures of the eye were withstanding the ageing process as well as, or even better than, the general cerebral structures—only 14 persons are unable to read, while 16 have obvious mental degenerative changes.

### Conclusion

We have been privileged to live in an age when much has been accomplished to preserve vision. Active trachoma to-day is almost non-existent in this country, and most of the acute and subacute infective lesions have their antidotes—a truly wonderful advancement for our generation.

Looking at the inmates of the Old People's Home one can see that it is not necessarily the number of years that counts, but rather the state of the tissues. Therefore it would seem that one of the most important things to do is to choose one's ancestors correctly!

Surgery can remove a cataract successfully and perhaps stabilize glaucoma, but prevention will always be better than cure.

Living in this fast-moving age of change the fundamental ophthalmological research unit must be linked on the one side with general medical research, and on the other with local clinical research. It is probably to the former that we may look for major advances, but each one of us in his own sphere must try to make some contribution, however small, to the many unsolved problems, and so alleviate that "Last scene of all, That ends this strange eventful history", that it may not be "Sans teeth, sans eyes, sans taste, sans everything".

## The Clinical Diagnosis of Sex

PRESIDENT'S ADDRESS

By C. N. ARMSTRONG, M.D., F.R.C.P.

I HAVE chosen the problem of sex for this Address because of present-day interest in the subject, and I propose to make a clinical approach to the problem.

### CLINICAL PROBLEMS OF SEX

The *physical abnormalities* seen often concern the external genitalia, but other situations arise. Most frequently the sex decided at birth becomes questioned when supposed hypospadias requires repair; signs of precocious puberty appear; a young girl develops male pattern hair or primary amenorrhœa; or a young male has testicles which fail to descend, possibly together with signs of deficiency of secondary male characteristics. Occasionally the surgeon questions the true sex fortuitously at operation. For example, a colleague operated for acute appendicitis on an 11-year-old girl who was found to have no uterus due to the presence of the Testicular Feminization syndrome. Lastly the true state may emerge from the exercise of "sixth sense". An elderly "woman" was admitted to the general ward of a hospital from an old people's home, and one of the patients objected on the grounds that she thought that the patient was a man. This patient turned out to be a case of true hermaphroditism.

The psychological problems fall mainly within two groups. *Transvestism* or *Eonism* can be present in a male who may have more or less pronounced male physical characters, and the opposite situation may arise in the female. *Homosexuality* includes individuals whose emotional libido is directed to another person of the same sex. The behaviour may be active or passive, or both active and passive.

It is in these forms that various clinical problems have reached me. The correct sex diagnosis in itself may be important to the patient for determining the pathology and treatment in appropriate instances, or for legal reasons associated with inheritance or athletic competition.

### THE CRITERIA OF SEX

Certain criteria may be applied in establishing the final diagnosis which I would say are: (1) Nuclear sex pattern; (2) gonadal status; (3) chemical evidence; (4) external anatomy; (5) psychological sex.

### NUCLEAR SEX

Normally, an X or Y spermatozoon fertilizes an X ovum. The female factor X is represented by 1 and there are 1½ male factors carried in the autosomes; the Y is blank. Thus XX amounts to 2 female factors against 1½ male—this gives a predominance of 2 : 1½ in favour of female and the result is female. X Y amounts to 1 female against 1½ male and the result is male. The basic sex is female, the male being a further development from this. Sometimes the genetic factors may not be constant; for example it has been suggested by Sachs that there are women who are XXX and there may be individuals, both male and female, who carry in the autosomes a higher value of male factors than is represented by 1½. It is not known by what means the undifferentiated gonad in the fœtus at 7 weeks is influenced to develop into a testis with the development of subsequent male characteristics. XX causes the cortical part of the gonad to be differentiated and the XY the medullary part. It is highly probable that genetic factors determine the sensitivity of tissues to hormones, abnormality of such sensitivity causing some types of intersex. Barr noted in nervous tissue an intranuclear satellite body only present in the female. In other tissues 30% to 70% of the cells of females were found to have a small body adjacent to the nuclear membrane compared with only 5% of a similar structure in males. Later Davidson and Smith found a projection or "club" in about 6 out of 500 polymorph nuclei from females and none in those from males. This work is important in the problem of intersexes since those individuals with chromatin positive cells would, if the theory that Barr's bodies are hetero-chromatin derived from two X chromosome is correct, seemingly have XX chromosomes. The presence of this body would thus indicate the genetic sex of the individual whatever might have been the ultimate somatic or psychological development.

*Gonadal status* was at one time naturally thought to be the most important. The gonads might seem to determine the correct sex of the individual, and in the past I think that they would have been accepted for the legal definition. Since the detection of the nuclear sex pattern in the various syndromes it can no longer be said that the gonad is the all-important factor.

*Chemical evidence.*—There is no doubt that hormones play a very large part in the

physical development and other features of the individual and their estimation is valuable in certain syndromes, for example the adreno-genital syndrome, and gonadal dysgenesis. I doubt whether it is possible at the present time to say, on purely chemical grounds, what might be the sex of an individual.

*External physical characteristics* are important in influencing our minds on the nature of an individual's sexual status.

*Psychological sex* is of particular importance when it is different from the main physical characteristics indicative of external anatomical sex. Transvestism is also named Eonism after the Chevalier d'Eon de Beaumont, who was a diplomatic agent of Louis XV, and was taken to be a woman, but proved at post-mortem to be a normal man. Transvestism is an inaccurate term for the description of such cases, for the preference to wear feminine dress is only one expression of a strong desire to become identified with women, and to be regarded as a female by society. Other characteristics of eonism are the fantasies of pregnancy, passionate longing for a maternal role, preference for feminine games and activities, and a desire for castration in an attempt to achieve anatomical resemblance to a woman. This preference for the feminine role is evident from early childhood.

The condition is relatively common, but second in frequency to homosexuality. It may be symptomatic of homosexuality or other perversions, but only a small proportion of homosexuals are transvestites. The conditions are probably quite distinct for these reasons: the crucial desire of the homosexual is for sexual relationship with a person of his own sex whereas the eonist is repelled by the physical aspects of such relations and responds with disgust and revulsion. If an active sexual life is led by an eonist it is more often an heterosexual one, as in the case of Chevalier d'Eon and Abbé de Choisy. The evidence for regarding transvestism as being of a constitutional nature, doubtless on a genetic basis, perhaps can be even more readily accepted than in the case of homosexuality, because it is a phenomenon manifested so early in life and, in most instances, there are striking feminine characteristics of physique. There is no sound evidence for accepting the contention of psychiatrists that it is due to a castration complex or other environmental psychological factors, e.g. female dominance in the home.

*Homosexuality*.—By contrast homosexuals as a rule do not want to change their sex, and identity. I am surprised that even recently published works on endocrinology (e.g. Wilkins) still make the statement that the psychological sex is that according to which the individual has been brought up; if this were so man would be the only animal dependent on his environment both for his sexual libido and for the survival of the race. Surely this is fantastic! To quote Broster, the sexual act is so instinctive that it has not even to be learned but must be of genetic origin. All my cases of boys and men with hypospadias, brought up as "girls" have a male psychological outlook. The present attitude to homosexuality is similar to the attitude in the past to physical and mental illness, although I think scientific opinion is coming round to the view that the condition can be one of genetic and not environmental determination.

## Spectrum of Sex

Fig. 1 has been drawn for me by Mr. D. P. Hammersley mainly from photographs of my own cases. It gives his impression of the stances and features of cases of intersex. Beginning at the red end of the spectrum on the left is a normal woman, which is the basic sex, passing to the deviations from the normal, through the intersexes, to the blue end of the spectrum, the normal man. Various intersexes may occur, mostly as a result of purely genetic factors and of hormone influence, itself of genetic origin or acquired, or of failure of the target organ to respond to hormones. Fig. 1 is not intended to be scientifically correct in all details; it does not include all the syndromes, nor have I grouped, for instance, cases of gonadal dysgenesis together. It represents the way the problem of gradation of sex, including psychological sex, impresses me. I have taken permissible licence in a Presidential Address: I know I shall be criticized for including disorders of psychological sex amongst the physical intersexes, but in my opinion it is where they should be and where they will eventually arrive.

## The Clinical Diagnosis of Sex and Management

I should like, after the above remarks, to return to the clinical problems. Firstly *the patient with female micturition and large phallus*. Is this individual, in whom often hypospadias is diagnosed, in fact a boy or a girl? The patient will be a boy if the nuclear sex is male, and external male characteristics are present with the exception of the hypospadias; testes may be present or undescended. He should be regarded as of male sex and the hypospadias repaired. The patient will be a girl if the nuclear sex is female, and female external characteristics and ovaries are present. This may not be evident before puberty, particularly in that type of female intersex without endocrine disorder. It is important in such cases to estimate the urinary 17-ketosteroids. If the ketosteroids are normal and the patient has a uterus and ovaries, and is young, I would advise plastic

surgery if required and the adoption, if necessary, of female sex. If the ketosteroids are unduly high the presence of the adreno-genital syndrome would be indicated; in such cases treatment with cortisone should be begun early so that the normal development of female characteristics can occur. The *patient with female characteristics and primary amenorrhœa with or without pubic hair and normal or slightly enlarged clitoris* may manifest the Testicular Feminization syndrome, Turner's syndrome or Swyer's syndrome. "She" may have male nuclear sex and retained testes, which abnormalities may be considered of academic rather than clinical interest. The fact that pubic hair is absent in the Testicular Feminization syndrome and not made to grow by testosterone suggests that the cause of the Syndrome is lack of response of the target organ to the male hormones for genetic reasons. In my opinion patients of all these types should continue as females but they could raise a difficult legal problem, particularly if inheritance or athletics were involved. Until this question is fought out in the court we do not know the legal position. *Cases of poorly developed male characteristics, poor masculine hair, small penis, small testes, and with or without gynæcomastia.* Like the last group they may be found to have nuclear sex opposite to the external anatomy. In Klinefelter's syndrome the nuclear sex is usually female, suggesting they are masculinized genetic females. Yet in fact the external anatomy is male, and spermatogenesis does rarely occur, so it is better to regard them socially as males. The only legal complication which may arise if they are regarded as males would concern such an individual who is also a transvestite or homosexual. Such patients have been put in prison for following their psychological sex libido, even when the nuclear sex is female. Again thus far all the facts have not been presented in court. Under this general heading there are also patients simply having poor masculine development of genetic origin or due to hormonal deficiency, and those boys with adipose gynandrism (Simpson). *Patients with psychological sex abnormalities* immediately raise immense problems. No one surely will contend, after scanning the whole spectrum of sex with all its physical inconsistencies, that it would be reasonable to assume that the psychological sex must correspond to the other sexual criteria. Prejudice is so deeply embedded that I doubt if we have reached a stage when the general public, or even the medical profession, would accept that psychological sex may differ from physical sex and can be of genetic rather than of environmental origin. If this view is accepted society can hardly be held responsible. I am prompted to ask, which is the more important, the body or the mind? The law of Great Britain, so far, is definite on this: it is the body. The law has no sympathy with the individual who has female psychological sex in a male body, nor has the general public. Without a physical background, it would be too much to expect the law to define sex merely upon psychological grounds. Although it may come to be accepted that there are individuals who are genetically psychologically of one and physically of the opposite sex and should be allowed to follow a life in accordance with their psychological sex, the registered sex of these individuals must, I would say, remain as determined by their physical characteristics.

## Conclusions

To sum up, my advice in intersex would be:

In cases of female micturition with large clitoris, always determine the sex by modern methods of nuclear sexing, ketosteroid excretion, &c., and advise that such cases be brought up as their correct sex. If they have been brought up in the wrong sex, carry out the necessary treatment, plastic, hormonal or both and advise that they change to their correct sex, even in adult life.

Those cases of intersex whose nuclear sex or gonads are not consistent with the external sex anatomy should be told nothing, but allowed to continue with the sex already assumed by their external body form which should be enhanced with treatment if possible. I would advise that the legal sex be that of the individual's external anatomical sex.

Where the psychological sex is opposite to that of the body, I think it is the duty of society to allow those individuals to live as their true sex emotion directs, provided it does not interfere with the welfare of other persons, but the legal registered sex should be that of the external anatomy.

In the case of transvestites, I should support the proposal of Dr. Peter Bishop, that a small committee should be set up to investigate such cases and have the legal right to advise any plastic surgery they consider necessary.

I shall conclude by quoting from Milton's "Paradise Lost."

> "For spirits when they please
> Can either sex assume, or both, so soft
> And uncompounded is their essence pure."

I wish to thank for their help Professor Martin Roth, Professor of Psychological Medicine, Dr. J. E. Gray, Lecturer in Anatomy, Mr. C. J. Duncan, Director of the Department of Photography, and Mr. D. P. Hammersley, Medical Artist, in the University of Durham.

## Julius Cæsar and the Falling Sickness

By TERENCE CAWTHORNE, F.R.C.S.

THE idea for this paper came when I was re-reading Shakespeare's "Julius Cæsar" at a time when I was preparing an article on Ménière's disease. In the very same Scene, and separated by but a few lines, the following statements are made:

JULIUS CÆSAR (*who has been talking to Antony about Cassius, ends by saying*):

"Come on my right hand, for this ear is deaf."

Then shortly after, in a discussion about Cæsar between Cassius, Casca and Brutus, the latter says:

"'Tis very like he hath the falling sickness."

Now it has always been assumed that Julius Cæsar suffered from epilepsy, but unilateral deafness and the "falling sickness", I thought, could mean Ménière's disease, and so I have been enquiring into the life and times of Julius Cæsar, with particular reference to his falling sickness.

As the 2,000th anniversary of his death by assassination fell on March 15, 1957, it seems an appropriate time to discuss his disorder and to recall his remarkable career which was brought to a brutal end by a determined band of his associates, many of whom he regarded as trusted friends. Though he was the most powerful and the most popular man in the civilized world, and though it was freely admitted that he had done more for the glory of Rome than any other citizen, he had by his remarkable and versatile talents shown up the lack of ability in many others; earning the envy and malice of those around him whose ambitions were so much greater than their often meagre abilities.

A Patrician by birth, his was one of the oldest and noblest Roman families, the Julians, and when his aunt Julia, who had married the Democratic or Popular dictator Marius, died, he said in the funeral oration:

> "On her mother's side Julia descended from the ancient Kings, on her father's from the Immortal Gods Themselves. Her mother and my grandmother, Marcia, descended from Marcius, the fourth King of Rome: while we of the Julian House trace back our origin to Venus Herself. In our family, therefore, we combine the Divine Right of Kings, who are the greatest among men, and the Worship of the Gods, to Whose Power even Kings must bow."

Though obviously proud of his family and possibly not unmindful of his destiny, he was no idle boaster when it came to his own deeds as set out in his "War Commentaries". It could never be said, however, that he hid his light under a bushel; indeed, it would have been difficult so to do as his great deeds shone out.

In view of his noble origin, it might be thought that Julius Cæsar would follow the Optimates or Republican Party, which included nearly all the Patricians. Instead he joined their opponents, the Populares or Democratic Party to which the middle classes

gave allegiance. In this, no doubt, he was influenced by his uncle, Marius, who had been the leader of the Populares. After the eclipse of Marius when Julius Cæsar was a youth, Sulla the champion of the Optimates came to power and dealt very severely with his political opponents. Fortunately for the Roman Empire, the youth Julius was left alone, though he had to travel abroad for some time.

Despite the great care taken to avoid any individual form of dictatorship in the Roman State, it gradually came about that political power was concentrated into the hands of a comparatively small group of Patrician families who saw to it that they dominated the Senate. Consequently many of the Laws which were passed favoured the Patrician and land-owning classes. Successful wars brought more slaves into Roman hands, and these slaves went to swell the estates of the landowners who were able to cultivate their land with cheap slave labour. The smaller farmers could not compete and sold their farms to seek their fortune in the capital, thus adding to the number of the "hangers on" and unemployed. Successive political leaders vied with one another to gain popularity, and the increasing inefficiency and corruption of both Parties were undermining the State, so that the time was ripe for a man with that rare combination of ambition and ability to rescue the Roman Republic from the slough of corruption and selfishness which was threatening to engulf it. Though we know that Julius Cæsar was the man to do this it took him fifty years of pushing, bribing, intriguing and fighting to convince his contemporaries of this. And even when he had succeeded, they could not forgive him and despite all he had done for them and for the State they murdered him; though they preferred to call it "tyrannicide".

This was a political blunder, for Cæsar was the one man who could have built upon the old foundation a solid and workable government. His assassination involved the State in fresh struggles and civil wars, until in the end it fell under the supremacy of Cæsar's heir and nephew, Augustus, who established a far more despotic rule than that which the so-called liberators had attempted to avert.

Born in the year 102 B.C., Cæsar was, thanks to his uncle Marius' influence, given, of all things, a senior religious appointment as Flamen Dialis at the age of 15. This gave him a seat in the Senate but precluded him from taking an active part in war or politics. This did not last very long and at 19 he went abroad, gaining experience in war as an aide-de-camp and as an orator and lawyer from the leading teachers in the Grecian Islands. This included an episode at the Court of King Nicodemus which later on was magnified by his opponents into a homosexual scandal. However, his conduct in more mature years shows that if this incident ever occurred it was but an adolescent prank, for Sir Charles Oman refers to him later as "the inevitable co-respondent in every fashionable divorce". Returning to public life in Rome at the age of 30 he achieved the coveted Consulship by the age of 42.

He was not too particular about the means he employed to reach this post which has been described as a "carnival of illegality and mob law, which made a fitting close to the whole of his demagogic career".

Once his Consulship was over he took over the pro-Consulship of the Gallic Provinces, at the same time forming an uneasy alliance with the financier Crassus and the ex-soldier Pompey. This was known as the Triumvirate and each was of equal Consular rank and power. Cæsar left for his Gallic Province and it was ten years before he returned to Rome, having in the meantime conquered the whole of Gaul, contained the Germanic hordes and invaded Britain twice.

Despite his previously slight military experience Julius Cæsar soon proved to be an exceptional leader in war. He was not only a great strategist and military tactician but he was also a leader of men. Many were the times that he, personally, led his men into battle, and he was often in the thickest of the fight. As an orator and as a politician he was unequalled and by sheer force of intellect he could persuade men to his way of thinking, equally well in committee, in the political arena or before a group of tired and even rebellious soldiers. Even the eloquent though vacillating Cicero, the silver-tongued orator, was compelled to admit that he had met his master in Julius Cæsar; but he never forgave Cæsar for this, and I believe that it was he, Cicero, who was behind the plot to kill Cæsar.

At the end of the Gallic campaign Cæsar fought his way back to Rome from which his opponents, the Senate (headed by Pompey) had fled, but four more years of fighting in Spain, Greece, Africa and again Spain were needed before he finally returned triumphantly to Rome.

During the year that was left to him he laid the foundation of a new autocracy headed by a Sovereign to rule the Roman Empire in the place of the Senate and the people. His

names have been immortalized in the month of July and in the title of Cæsar, Czar and Kaiser. He forgave his political enemies; but this was his undoing, for they could not forgive him.

As a young man he was undersized and delicate, but he grew up to be virile, tough and even licentious. Though he loved luxury and power, he never over-indulged in eating or drinking, and between the ages of 40 and 55 lived the hard life of a soldier on campaign. Always in the public eye, any disorder, infirmity or even slight accident is sure to have been noted and even magnified. We have heard of his baldness and of his amours, and even when he stumbled and fell when disembarking on to African soil during the Civil War this was noted by Plutarch. I am sure that if he had been subject to real epileptic fits we would have heard much more about them than has come down to us from the writers of those times.

Our main source of information about Cæsar's "falling sickness" comes from "Plutarch's Lives" in which it is mentioned three times.

The first was part of a general description of Cæsar—

> "he was lean, white and soft-skinned, and often subject to headache, and other while to the *falling sickness*, the which took him the first time, as is reported, in Cordoba."

Now Cæsar was three times in Spain. The first time was before he was Consul, the second in the early stages of the Civil War before he defeated Pompey at Pharsalus, and finally after the African campaign when he was dealing with Pompey's son and his followers. This must refer to the second campaign in Spain as Plutarch's next reference to the sickness is in the African campaign at the battle of Thapsacus against King Juba and Scipio. When he did not take his usual place in the forefront of the battle Plutarch says:

> "For as he did set his men in battle the falling sickness took him, whereunto he was given, and therefore feeling it coming, before he was overcome withal, he was carried into a castle not far from thence where the battle was fought, and there took his rest till the extremity of his disease had left him."

Plutarch's third reference is to the time when the populace offered Cæsar the Emperor's crown and he refused it three times:

> "Notwithstanding it is reported that afterwards, to excuse this folly, he imputed it to his disease, saying that their wits are not perfect which have this disease of the *falling evil* when standing on their feet they speak to the common people, but are soon troubled with a trembling of their body and a sudden dimness and giddiness."

It may be noted that in none of these three statements is there any reference to loss of consciousness, to foaming at the mouth, to twitching of the face or limbs, or indeed to any of the other manifestations of epilepsy.

Plutarch, the Greek philosopher and biographer, was born in the reign of Claudius, half-way through the first century, A.D. He wrote in Greek and his most famous work, his "Lives," compares and contrasts the Greek and Roman heroes. His is the most contemporary and the fullest life of Cæsar.

There is another by Suetonius, the first in his series of "The Lives of the Cæsars." This was written some seventy years after Plutarch. Suetonius had the advantage of being Secretary to the Emperor Hadrian and in this position had access to Imperial Archives. His "Life of Cæsar", written in Latin, makes but one short reference to Julius Cæsar's ailment—"He was twice attacked by the *falling sickness* during his campaigns".

As might be expected Cæsar himself makes no reference to this sickness in any of his works, nor is it mentioned by Cicero, Lucan or Dio Cassius.

Shakespeare's source of information about Julius Cæsar came from Sir Thomas North's translation of "Plutarch's Lives"; and it was Sir Thomas North who coined the term "*the falling sickness*". He did not translate direct from the Greek, but from the French of James Amyot, Bishop of Auxerre. There is no mention in Plutarch, or in any other Greek or Roman author, of Cæsar being deaf, even in one ear.

The only reference I can find to Julius Cæsar's deafness comes from George Wherry in "Notes and Queries" (1909), Series 10, Vol. XL, p. 243.

> "*Julius Cæsar's Deafness*—Shakespeare makes Julius Cæsar deaf in the left ear. To Mark Antony Cæsar says: 'Come on my right hand, for this ear is deaf'; and his attacks of epilepsy are also noted in the play—'He hath the *falling sickness*'. It is quite possible that attacks of giddiness associated with Ménière's Disease of the ear may have been mistaken for epilepsy. The Romans were familiar enough with

epilepsy, which they called 'morbus comitialis', from the attacks witnessed in the Forum or Senate House which broke up the Assembly; and it is unlikely that aural vertigo was understood at that time."

Where, then, did Shakespeare get his reference to Julius Cæsar being deaf in the left ear? It has been suggested that there might be some political significance in this, but it cannot be in the modern sense, for the term "Left Wing" and "Right Wing" only became significant in the Assembly of the French Revolution. Again, could it be that Cæsar was suggesting that he was going to forget what had just been said? But as he had just been doing all the talking and very little listening, there is little point in this suggestion. As there does not appear to be any mention of Cæsar being deaf in any of the references available to Shakespeare he may have put this in so as to add a touch of realism to the part. We know that Shakespeare always made his great historical figures behave like ordinary human beings; and indeed it is just that homely touch which makes his characters live. It could well be that Shakespeare knew someone or possibly more than one person who was troubled with the "falling sickness" and deafness, and that he introduced the deafness in one ear in order to make Cæsar like other men. There is no reason to suppose that the deafness was brought in to help the stage business.

But even if we are to deny Cæsar's deafness on the grounds that we have only Shakespeare's word for it, we are still left with his "falling sickness". Plutarch, writing in Greek, refers to this as "Epileptikois", a term used in those days for any seizure that caused the sufferer to fall down and be helpless. It is not surprising that many writers translated this as epilepsy, and so the term "falling sickness" and epilepsy have been loosely regarded as the same thing. Suetonius, writing in Latin, uses the term "morbus comitialis", the disease which, when it attacked a member of a committee, ended the meeting. Clearly such a description could include epilepsy, a stroke, a heart attack and also an attack of Ménière's disease.

Now, as Cæsar's mental and physical powers remained unimpaired between attacks, it seems unlikely that they were caused by heart disease or a cerebral catastrophe. This leaves epilepsy and Ménière's disease.

When the "falling sickness" first overcame him, Cæsar was in the early fifties, a common time for Ménière's disease to start. As the most famous man of the Ancient World, there was no shortage of writers and poets to publicize his failings as well as his strength. Had he really suffered from epilepsy it is difficult to believe that it would have been passed over in the few words that have come down to us. Nor can it be said that the Romans were unacquainted with epilepsy, for here is a description given by Lucretius of an epileptic fit:

"Oft times with violent fits a patient falls,
As if with thunder struck; and foams and bawls,
Talks madly, shakes, moves here and there, breathes short,
Extends and tires his limbs with antic sport;
. . . . . .
His weakness wears and he forgets his pain;
His strength, his life, his sense return again."

Had Cæsar suffered from major epileptic seizures, surely these sensational attacks would not have been passed over so lightly by the careful biographer Plutarch, or by the gossip Suetonius.

Had these attacks been something more serious than a labyrinthine disturbance, they must have left a greater mark on the man who, for the last fifteen years of his life, extended and dominated the Roman State. A man, moreover, who could at the end of twelve years' continuous fighting and political intrigue take time off to share with Cleopatra one of the great love affairs of the world.

That it could have been a minor form of epilepsy cannot be denied, though sufferers from *petit mal* so often are troubled also with bad tempers, fits of depression, or some form of neurosis and there is nothing to suggest that Cæsar was ever affected in any of these ways. Coming on at that time of life and not leading to any deterioration of mental or physical powers it is, in the light of our present knowledge, much more likely to have been a benign disorder such as Ménière's disease.

We are still left with the problem of deafness, and though I have been unable to trace any contemporary account of Cæsar being deaf, I shall always be grateful to the memory of Shakespeare—not only for the plays which we enjoy, but for suggesting an alternative and, to me, plausible cause for Cæsar's "falling sickness".

[*October* 2, 1957]

## DISCUSSION ON HIATUS HERNIA

**Mr. Norman C. Tanner** (London):

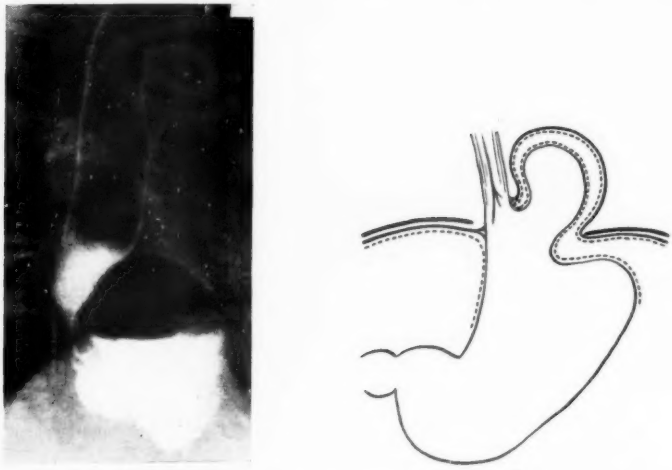
Hiatus hernia is a deformity which may exist through life without producing any notable disturbance, or it may give rise to complaints varying from slight breathlessness on exertion to the most severe dysphagia. With large hernias, cardiac and pulmonary symptoms such as palpitations or breathlessness on exertion may be present. At times, the main symptoms may be the result of distortion of the contents of the sac, such as gastric volvulus with transient gastric obstruction. Often the symptoms of a patient with a hiatus hernia are due to another condition, e.g. peptic ulcer, biliary disease, or abdominal carcinoma (Tanner, 1955*a*). The most important effects of hiatus hernia, however, result from reflux of gastric juice, leading to congestion or even deep ulceration of the gullet. The symptoms are heartburn, pain, anæmia and, when cicatrization takes place, dysphagia.

The treatment of hiatus hernia is nearly always medical in the first place. Reduction of the volume of gastric content is aided by taking small frequent meals. Alkalization diminishes the erosive powers of the juice. Reflux is minimized by avoiding recumbency and stooping and by diminishing intra-abdominal tension. Weight reduction and avoidance of belts and corsets significantly lower intra-abdominal tension. Stricture dilatation is occasionally needed in the aged. Surgical repair is indicated as a prophylaxis against œsophagitis in infants and young people. In young adults with large hernias, repair may be required in order to improve respiratory and cardiac efficiency.

The ideal surgical treatment of a hiatus hernia is repair of the hernia before œsophageal damage has occurred. Once deep œsophageal ulceration and fibrosis have taken place, the mechanism of the cardia is so distorted that simple repair is less effective, though some success may follow repair even in these late cases.

*Lines of Treatment*

For the cases complicated by œsophageal ulcer and stricture, a number of lines of treatment are open to the surgeon. A certain cure of œsophagitis is to transect the gullet above the stricture and anastomose it to a Roux loop of jejunum with or without gastrectomy, but this is a severe procedure. A less severe operation is to resect the stricture and part of the upper stomach, and anastomose the œsophagus to the stomach remnant (upper partial gastrectomy) (Tanner, 1955*b*). The gullet is transected just above the stricture, for the gullet here is fibrous and, unlike the normal gullet, even its outer coat will hold sutures well. As much stomach as can be safely removed is resected and the vagus nerves are transected in order to reduce the acidity of the gastric juice, which will now be regurgitated even more freely than before. The post-vagotomy pylorospasm is best overcome by a coincident gastro-jejunostomy to the pyloric antrum. A pyloroplasty or Ramstedt pylorotomy helps, but is less effective than gastro-jejunostomy.



Other operations of still less severity are lower partial gastrectomy, and simple vagotomy combined with gastro-jejunostomy. If lower partial gastrectomy as for duodenal ulcer is done, the stomach stump should be anastomosed to the jejunum rather than to the duodenum owing to the desirability of rapid emptying of the gastric remnant. If a duodenal ulcer is present in addition to the œsophageal stricture, this operation is even more likely to be beneficial. Finally there are various experimental methods such as replacement of the cardia mechanism by an isolated jejunal loop (Merendino and Dillard, 1955), but of which only short-term results are available.

*Operative Technique*

I prefer to approach the hiatus from the abdomen, not only because 20% have an accessory intra-abdominal lesion which is in greater need of treatment than the hernia, but also because the direct view of the crural origins is more convenient for the repair (Tanner, 1955*a*). With good relaxation, aided by excision of the xiphoid process and mobilization of the left lobe of the liver, a good view of the hiatus can be obtained.

In these cases the peritoneal reflections on to the gullet and the phreno-œsophageal ligaments are elongated and thinned, and therefore useless for repair. They are freely

excised until the muscle of the œsophageal hiatus and of the adjacent cardia is laid bare. Only in certain para-œsophageal hernias without reflux is the phreno-œsophageal ligament strong and worth retaining (Fig. 1A, B). The vagus nerves are carefully preserved, since

A B

FIG. 1.—A, X-ray of para-œsophageal hernia without reflux. B, The appearance noted at operation on certain para-œsophageal hernias. The phreno-œsophageal ligament is intact on part of the circumference, but deficient elsewhere, usually to the left side.

otherwise a post-vagotomy pyloric dysfunction will lead to reflux as a result of gastric retention. It is important to dissect the hiatus margins free all round, as otherwise a pad of fat may be left particularly posteriorly, which may be the weak spot initiating a recurrence. Indeed, I believe that the only reason for the improved results when repair posterior to the gullet was instituted, was that the posterior margin of the hiatus was being freed of fat and peritoneal pouches for the first time.

*Types of Repair*

I have repaired the enlarged hiatal opening by several methods. The first was by suturing the margins together in front and behind the gullet by wide interrupted non-absorbable sutures. This method has the disadvantage that some phrenic nerve branches are caught in the sutures at times, and some degree of muscle strangulation may occur. The next method was by imbrication. At operation it can be seen that the muscle fibres to the left of the gullet take origin posterior to the right fibres and so I draw the right margin to overlap the left one, again either anterior or posterior to the gullet (Fig. 2). The third method was by an

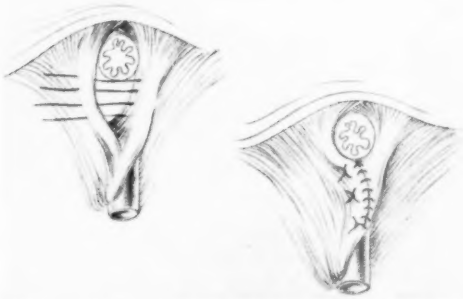


FIG. 2.—"Imbrication" operation posterior to the œsophagus. Note that the fibres of the left margin take origin deeper than that of the right; the overlapping exaggerates this anatomical position.

anterior "darn". If one puts a finger into a normal hiatus, as for example in the operation of vagotomy, the finger is not held by a ring of tissue, but enters a tunnel. About 3 cm. of finger is held posteriorly against the aorta by the fascia spreading from the diaphragm to run down between the anterior margins of the hiatus and the gullet. I believe an anterior repair should be made in an endeavour to reproduce this fascia and exert an even backward pressure on the lower few centimetres of the gullet. The chance of repair will obviously be greater if a canal is formed for the gullet rather than a circular hole (Fig. 3).

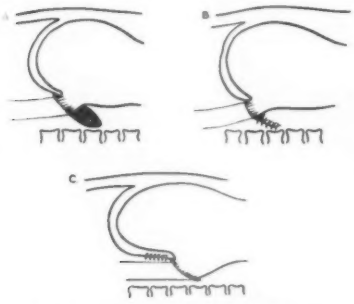

FIG. 3.—Lateral view of hiatus repairs. The posterior repair (B) produces a small hole in a muscle sheet; the anterior repair (C) can be made to produce a tunnel-like passage for the œsophagus.

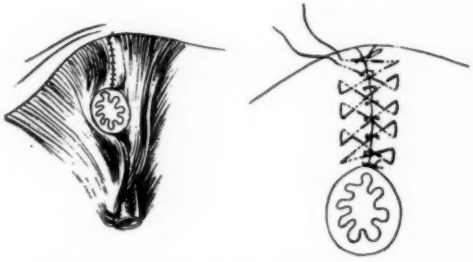

FIG. 4.—Anterior "darn" repair. The edges are sutured together and the sheet of muscle in front of the œsophagus is reinforced with a monofilament nylon darn.

After dissecting the hiatus margins free, I suture the medial edges of the anterior margins together. This gives a thin sheet of longitudinal muscle in the area in which I desire to produce a strong fascia. I now introduce into this sheet of muscle a transverse darn of fine nylon, No. 5, on a very fine or atraumatic needle. This should provide the type of strong tissue desired, even if some of the muscle fibres should degenerate. The darn is probably more likely to remain fixed and intact than a graft of nylon mesh sewn on the surface, though that is an alternative procedure (Fig. 4). The operation is completed by replacing the gullet into the mediastinum and fixing it in position by fine sutures between cardia and the new hiatus margin. These latter sutures replace the lost phreno-œsophageal ligament. When the gullet is in position, the stomach is automatically restored to its normal subphrenic position and the normal œsophago-gastric angle is also reconstituted.

## RESULTS

In 1955 I reported the results in a series of our cases for posterior repair as follows (Tanner, 1955*a*):

HIATUS HERNIA ALONE

| Posterior repair | Good | Improved | No better |
|---|---|---|---|
| Traced 47 | 31 | 12 | 4 |

Dr. B. F. Swynnerton at St. James' Hospital and Mr. J. E. H. Pendower at Charing Cross Hospital have reviewed the cases I have personally operated on in the last three years, cases requiring a gastrectomy or associated with frank œsophageal stenosis being excluded. The results may be tabulated as follows:

POSTERIOR REPAIR (MAINLY IMBRICATION)

| Number interviewed | Satisfactory | No better |
|---|---|---|
| 16 | 12 (75%) | 4 |

ANTERIOR REPAIR (IMBRICATION AND DARNS)

| Number interviewed | Satisfactory | No better |
|---|---|---|
| 28 | 24 (85%) | 4 |
| (Darns 17 | 15 (88%) | 2) |

10 of the patients operated upon between six months and three years previously at Charing Cross Hospital were X-rayed. Of the 10, 9 were satisfied with their results and none of these showed a hernia by the usual radiographic methods employed, although one still had reflux. The unsatisfactory case had both reflux and a small recurrent hernia on X-ray.

*Contra-indication to Hiatus Repair*

I have mentioned gross œsophageal ulceration and shortening as contra-indications. Obese patients should reduce weight, and maintain the reduction after operation. A difficult case is that in which the lower œsophagus is lined with gastric mucosa. The hiatus may also be weak in such patients. Repair here will make matters worse, but these cases can be excluded by careful pre-operative œsophagoscopy. I would finish by emphasizing that no patient should be operated on without a careful preliminary œsophagoscopy. Carcinoma must be excluded and if abdominal repair is to be undertaken one must be sure that the gullet is mobile and that there is no penetrating ulcer. Penetrating ulcers of the gullet require an abdomino-thoracic approach.

**Mr. R. H. Franklin** (London):

The difficulty in treating hiatus hernia is that surgery is called for to deal with the complications which may be the result of the hernia, and these are so varied that they rule out the possibility of a standard operation for all patients. The symptom-free hiatus hernia which is discovered incidentally should not, as a rule, require treatment. The subject is made more difficult by the fact that reflux œsophagitis with all its complications is sometimes seen in patients in whom no hiatus hernia can be demonstrated. Infants constitute a special problem and will not be considered here.

*Symptoms associated with Hiatus Hernia*

The symptoms which lead the patient to seek advice are pain, dysphagia and hæmorrhage, and these symptoms may occur separately and in all degrees of severity. When pain is the only symptom, an attempt should be made to relieve the patient by a conservative regime, the most important thing being to impress on the patient the necessity for avoiding anything which favours regurgitation. Thus, posture to prevent regurgitation must be kept up at night as well as during the day-time, and rather than trying to raise the shoulders on pillows it is often easier to raise the head of the bed. Other factors which tend to increase the abdominal pressure, such as tight belts or abdominal supports, should also be avoided. Weight reduction in the case of obesity is very important. It is only when a thorough course of medical treatment has failed that operation should be undertaken in those patients who are suffering from heartburn as the only symptom and in whom there are no other complicating features present.

*Indications for Operation*

Operation is indicated if there is a marked stricture at the lower end of the œsophagus; if pyloric stenosis is present due to a duodenal ulcer; or if the part of the stomach in the chest has itself developed a chronic ulcer. In all these cases, operation is likely to be the only treatment which will afford the patient any permanent relief. In some patients suffering from duodenal ulcer associated with spasm, pain from reflux œsophagitis may be the presenting symptom if they happen to have an incompetent cardia. If the ulcer of the œsophagus resulting from this is small it may be possible to give complete relief by means of a straightforward abdominal partial gastrectomy directed at the duodenal ulcer. But this method of treatment should not be regarded as sufficiently reliable to effect a cure in those patients who have already developed severe damage to the lower œsophagus, and it has the disadvantage of making any subsequent operations for the strictured part of the œsophagus more complicated. The types of operation which may be required in dealing with reflux œsophagitis and its complications are the following:

*Operation to Improve the Anatomical Arrangement of the Cardia*

This procedure is suitable for patients who have failed to respond to medical treatment and whose main symptom is persistent pain. (A severe fibrous stricture or severe hæmorrhage necessitates more drastic procedures.)

The aim of the operation is to return the stomach to the abdomen and to keep it in place by suturing the phreno-œsophageal ligaments to the undersurface of the diaphragm, at the same time restoring the normal angle of insertion of the œsophagus into the stomach. In addition the vagi are divided with the object of reducing the acidity of the gastric contents; to overcome any ill-effects from the vagotomy and to ensure rapid emptying of the stomach the pyloric sphincter is also divided. This last procedure has the added advantage that it may bring to light the unsuspected finding of a duodenal ulcer or of pyloric obstruction.

The operation is carried out by a left-sided thoracic approach. The lower œsophagus is

inspected after division of the left pulmonary ligament and a radial incision made in the diaphragm from the costal margin towards the hiatal opening, the incision ending just short of the right crus so as not to damage this structure. The stomach and duodenum are inspected and the hernia demonstrated by passing a hand through the hiatus from the abdomen. If the conditions are suitable for carrying out the operation contemplated, the œsophagus is mobilized as far as the root of the lung, the vagi being divided during this procedure. The peritoneum passing from the stomach to the undersurface of the diaphragm is divided. The phreno-œsophageal ligaments are demonstrated and the stomach kept in place in the abdomen by a series of interrupted thread sutures passing between the phreno-œsophageal ligaments close to the œsophagus and the undersurface of the diaphragm. The sutures are all passed before they are tied. It is often possible to restore the angle of insertion of the œsophagus in the stomach either by stitching the fundus to the undersurface of the diaphragm or by a stitch between the stomach and the left edge of the lower end of the œsophagus. The pyloric sphincter is now divided in much the same way as in a Ramstedt's operation. The opening in the diaphragm is closed meticulously using interrupted sutures of thread, having made sure that hæmostasis is complete.

*Total Gastrectomy and Restoration of Continuity by Roux-en-Y Anastomosis*

This is a satisfactory procedure to carry out when there is a marked stricture of the œsophagus associated with a duodenal ulcer. The operation is carried out through a left-sided abdomino-thoracic approach, excising the lowest 4 cm. of the œsophagus together with the stomach. The spleen is normally left undisturbed. Continuity is restored by means of a Roux-en-Y anastomosis bringing the mobilized segment of small bowel behind the transverse colon. It is often convenient to close the end of the small bowel and to make an end-to-side anastomosis with the œsophagus. Great care is taken to approximate the diaphragm to the small bowel to prevent the possibility of development of a diaphragmatic hernia. At first sight this may seem a very drastic procedure to carry out, but for a patient who has a marked stricture of the œsophagus associated with chronic ulceration of the duodenum, possibly with pyloric stenosis, it is the only procedure likely to be of lasting benefit. Provided care is taken to instruct the patient to take small frequent meals and to persist in his taking fat, an improvement in comfort will normally take place after two or three months.

*Excision of Part of the Œsophagus with Restoration of Continuity by making a High Œsophagogastric Anastomosis*

This procedure is called for when there is a considerable degree of œsophageal stricture, possibly situated high up in the chest with a lot of œsophageal shortening, wnile at the same time the rest of the stomach and duodenum are quite healthy.

In this operation, which again can be carried out by the left-sided abdomino-thoracic approach, the stomach is mobilized, leaving the spleen in position, care being taken not to damage the hiatus. The œsophagus is mobilized up to a point above the arch of the aorta, the part immediately behind the arch having to be done blindly, but if this part is healthy the mobilization can be carried out quite satisfactorily from the left side. The œsophagus is divided just above the arch of the aorta and the stump of the œsophagus displaced to the left of the arch and anastomosed to the fundus of the stomach. The pyloric sphincter is divided. The radial incision in the diaphragm is carefully closed as before and having left the hiatus itself intact, it is easy to approximate this snugly to the stomach.

Post-operatively, the patient is advised to guard against regurgitation by paying attention to posture. Provided this precaution is taken there does not seem to be a particular tendency for these patients to develop œsophagitis higher up, but it may be pointed out at this stage that secondary œsophagitis occasionally occurs whatever operation has been done and even after total gastrectomy some patients develop a very brisk alkaline œsophagitis.

*Partial Gastrectomy together with Fixation of the Stump of the Stomach in the Abdomen*

The indication for this is where there is an ulcer of the stomach or duodenum with associated symptoms of reflux œsophagitis, but in which there is permanent damage of the œsophagus in the form of fibrous stricture formation or severe ulceration.

In this operation the approach as before is by a left-sided abdomino-thoracic incision with thorough mobilization of the stomach and preservation of the hiatus. A partial gastrectomy is usually carried out by Polya's method. The remains of the stomach are fixed below the diaphragm by suturing the phreno-œsophageal ligaments to the undersurface of the diaphragm.

**Mr. Vernon C. Thompson** (London):

During the last ten years there has been so much discussion on hiatus hernia and so much divergence of opinion that the problem has become unduly complicated. I think it should be simplified by regarding hernias through the œsophageal hiatus of the diaphragm in the same

way as other hernias. In general, the principles underlying the treatment of hernia are that the contents should be reduced, the peritoneal sac excised, and the defect in the abdominal wall repaired. The fundamental difference between a diaphragmatic hernia and a hernia through the superficial abdominal wall is that the approach to the former is in my opinion best made from above the diaphragm.

There are three types of hiatus hernia:

(1) Sliding.
(2) Para-œsophageal.
(3) Combined.

Like other hernias they may be symptomless but their complications are serious and may lead to the death of the patient.

Strangulation is rare, but hæmorrhage, ulceration and obstruction are not uncommon, and reflux œsophagitis is a particular complication. These complications are sufficiently common to justify a radical repair in all patients with symptoms unless there is some special contra-indication. The need for operation is determined by the patient who is the best judge of the severity of the symptoms.

To the question whether the operation can be carried out successfully without appreciable morbidity or mortality, my answer is that it can. In the 55 patients on whom I have operated there have been no deaths. The ages range from 6 months to 77 years and many of the cases have been complicated. Since 1950, with an improved technique, I have had only one recurrence. In 2 cases, a sleeve resection for a penetrating gastric ulcer was carried out in addition to the repair. In others the œsophagus was densely matted to the mediastinal structures and in 2 there was an ulcer penetrating the pericardium. In my view there is no place for palliative physiological operations on the stomach done below the diaphragm for this condition. The most severe œsophagitis that I have ever seen was in a patient who had had a subtotal gastrectomy. The lower half of the œsophagus was raw and bleeding so much that the patient's life could only be maintained by frequent blood transfusions. This patient was treated by total gastrectomy and œsophago-jejunostomy using a Roux loop. Another patient who had had a gastro-enterostomy was bleeding to death from a jejunal ulcer. The jejunal ulcer was situated in his chest. In addition to repairing his hernia it was necessary to undo the gastro-enterostomy and resect the jejunal ulcer. Provided the œsophagus has not become too short as a result of fibrosis to allow the hernia to be repaired, there seems to me to be no serious difficulty in dealing with hiatus hernia. The essential points in the technique are that after reduction of the hernia, the œsophagus should be anchored below the diaphragm and the defect in the hiatus should be repaired by approximating the right and left crura of the diaphragm behind the œsophagus. If the hernia is satisfactorily repaired reflux œsophagitis will soon cure itself and strictures can usually be successfully treated by dilatation. The most satisfactory method of treating a stricture is by self-bouginage with gum elastic bougies. This applies to children as well as adults.

The difficult problem in dealing with hiatus hernia occurs when the œsophagus has become so shortened by fibrosis that reduction and repair become impossible. The cases in which the lower œsophagus is lined by gastric mucosa fall into the same category. There are two possible lines of treatment. One is the avoidance of decubitus, the sucking of alkali tablets, and self-bouginage; the other is resection. The first line of treatment is only palliative, and often disappointing. If the stricture is dilated it permits greater reflux and tends to increase the œsophagitis with its complications of pain and hæmorrhage. Resection is drastic but sometimes essential. Resection of the stricture with a low œsophago-gastrostomy on the left side of the chest is unsatisfactory as it merely reconstitutes the original cause of the œsophagitis. If, however, the anastomosis is made high up above the arch of the aorta on the right side of the chest so that the fluid level in the stomach is well below the level of the anastomosis, no regurgitation or œsophagitis occurs. The alternative is to use a loop of the jejunum or colon to replace the lower end of the œsophagus. I have had no experience of using the colon for this purpose and I am not satisfied that the jejunum is entirely satisfactory, because the type of peristalsis in the loop is not a forward emptying movement but one of to-and-fro mixing so that the œsophagus above the anastomosis is constantly bathed in digestive secretions. These secretions may not be as irritating as pure gastric juice but nevertheless they have digestive properties. I discovered this years ago when using subcutaneous jejunal loops for high resections of the œsophagus in carcinoma. I have seen œsophagitis and stricture develop after total gastrectomy and œsophago-jejunostomy with a Roux loop. Although one is naturally reluctant to put most of the stomach in the chest, especially in a child with the hope of a normal lifetime, I have yet to see œsophagitis or stricture in a really high œsophago-gastric anastomosis. These children eat and live normally. My present practice, therefore, when resection is necessary is to mobilize the stomach through an abdominal incision and bring it up for a high anastomosis through a right thoracotomy.

**Mr. Donald Barlow** (London):

In this problem, the first essential is an accurate diagnosis, and the exclusion of other conditions such as carcinoma, and achalasia. For this purpose I use a high-power distally illuminated telescope (Fig. 1). With this instrument there is a brilliantly lit close-up view and accurate biopsy is also possible. Hiatus hernias are common in those past middle life especially if they are fat and corseted. Many patients can be treated conservatively. They must discard their corsets, avoid stooping, and avoid recumbency at night. For this latter purpose, I advise the use of a specially upholstered bed chair (Fig. 2).

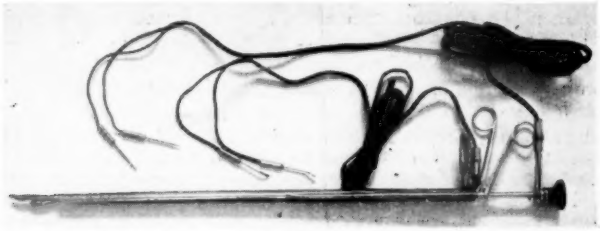

FIG. 1.—Barlow's high-power distally illuminated œsophageal telescope.

FIG. 2.—Upholstered bed chair to prevent gastric contents entering œsophagus and lungs at night.

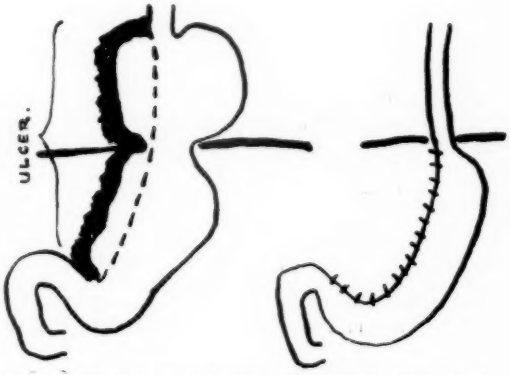

FIG. 3.—Method of repair when huge gastric ulcer extends into hiatus hernia.

*Hernias Requiring Operation are:*

(1) Those in children and young people. This is necessary to prevent ulceration and stricture later in life. Good repair can be effected via the abdomen because, since there is no ulceration, reduction is easy and the limbs of the right crus are easily defined for suture.

(2) Those with œsophago-gastric ulceration with or without stricture. Because of adhesions, the operation must be through the chest and full mobilization obtained. If mobilization is attempted via the abdomen, the risk of leakage and empyema is grave. In the repair of a simple hernia, it is usually possible to preserve the vagi, and there is no post-operative pylorospasm. If there is ulceration, both vagi may be destroyed, and pyloroplasty or gastro-enterostomy through the diaphragm is advisable after the repair.

(3) Those with associated gastric or duodenal ulcers. Pyloric stenosis and gastric or duodenal ulcers are often missed. Insufficient barium may pass to demonstrate these lesions owing to the dysphagia. Duodenal ulcer with varying degrees of pyloric stenosis exists in about 20% of hernias with ulceration at the cardia.

The approach in these cases is either through the chest and diaphragm as in (2), or by a thoraco-abdominal incision. The following alternative procedures may then be performed:

(*a*) Repair plus gastro-jejunostomy.

(*b*) Splitting and opening of the œsophageal muscle, intramuscular resection of the ulcer and stricture with mucosal anastomosis and repair of muscle, followed by gastro-jejunostomy.

(*c*) Resection of whole stomach including the ulcers at pylorus and cardia and followed by a Roux-en-Y anastomosis. Polya gastrectomy is rarely indicated.

When there is a gastric ulcer extending into a hiatus hernia, the condition can be cured through the abdomen without thoracotomy. After "cracking" the ulcer off its bed which is left, the hernia is easily reduced. The ulcer edges are then excised and sutured to make a tubular stomach (Fig. 3).

(4) Those with very large hernias with pain due to volvulus or smaller hernias with pain and discomfort due to the trapping of wind. In this group are patients with tachycardia.

"Spill-over disease", i.e. aspiration infection of the lungs is more common than is supposed, occurring in all types of chronic œsophageal or pyloric obstruction. Its presence constitutes a strong reason for operation.

(5) Those with carcinoma in a hiatus hernia. Radical thoraco-abdominal surgery with Roux-en-Y repair is usually indicated.

(6) Children and even young babies may have hiatus hernias. These should be repaired at an early age. Only too often they present when ulceration and stricture have resulted in prolonged malnutrition and even rickets and scurvy. These patients demand great care and patience. Dilatations over a long period may have to be performed but surgery should not be unreasonably delayed. A child's œsophagus may appear grossly shortened but when the ulcer is freed, it is amazing how the œsophagus can be extended.

## BOOK REVIEWS

**An Introduction to Psychopathology.** By D. Russell Davis. (Pp. viii + 388. 30s.) London: Oxford University Press. 1957.

It is refreshing to read a book on psychopathology which is not a formal recitation of Freud's theories. The author has worked in both a psychological and a clinical framework, and this book is the logical outcome of applying his experience in the first to the problems he met in the second. The exposition is clear, and full without being repetitive. The chapter on disorders resulting from brain lesions is particularly good. There are few criticisms to be made except perhaps that cross-laterality should be discussed in the section dealing with handedness; and that the association of stammering with left-handedness is not as certain as is suggested.

The usefulness of a book of this standard is immediately apparent in more than one context. It is clear enough to be understood by clinical psychologists, and indeed is an expansion of lectures given to undergraduate students of psychology. It should be a most helpful book to the medical student who is beginning psychiatry, and is sometimes unable to see what connexion his clinical studies have with the lectures given to him previously by an academic psychologist. It deserves a much wider public than this, however, for it shows the cornerstones of twentieth century psychiatry, and puts in perspective, without heat or bias, the sad determinist philosophy which once was all we had.

The book is agreeably produced and has an excellent index.

**The Evolution of Medical Education in the Nineteenth Century.** By Charles Newman, M.D., F.R.C.P., Dean of the Postgraduate Medical School of London. (Pp. 340. 30s.) London: Oxford University Press. 1957.

In medicine as in politics we are all heirs of, and often prisoners of, our history. This fascinating and erudite book on medical education in the nineteenth century appears therefore at a most opportune time when the way is open, as a result partly of the compulsory preclinical year, partly of the new regulations of the General Medical Council, for greater freedom for experiment in the content and technique of medical education. No one who is concerned with such experiments can afford to ignore this book. All could read it with profit. That is not to say that it is all gold and no dross—this would be too much to ask. But for the gold first.

The first 133 pages are medical history at its best, and delightful reading. The author starts with an account of medical education and practice in England at the beginning of the nineteenth century. Staggering to the modern mind is the extent to which physicians relied on symptoms to the almost total neglect of physical signs. This is so well described and illustrated that it is easy to appreciate the greatness of the revolution in medicine initiated by French pathologist-physicians with Bichat and Laennec as the leaders, when they introduced the science of clinical signs controlled by morbid anatomical findings. This paved the way in this country for the discoveries of the great Guy's physician- and surgeon-pathologists of the early and middle years of the century.

The real, though limited, advance in medical education that the Apothecaries Act of 1815 meant is well brought out. It is interesting to note that at this time five-sixths of the general practitioners of the country were surgeon-apothecaries, and that the College of Physicians by its unwise attitude to the 1815 Act cut itself off from general practitioner education for half a century. Of outstanding interest also are the extensive extracts from the Guy's clinical notes from 1823 to 1865, and the author's opinion of the importance in medical education of Students' Clinical Societies. Mention is made of the formation of the Guy's Clinical Society in 1836 and the Abernethy Society at Bart's in 1832. There is no note, however, that the oldest student medical society in London was formed by students of the Middlesex in 1774 "at the expense of their own candles".

After the brilliant opening comes a long dull patch from page 134 to page 193 dealing in detail with the prolonged tussles and the 17 Bills introduced before the final passage of the Medical Act of 1858. The later chapters on the ideal of the "safe general practitioner" which had such a profound influence on medical education, and on the rise of laboratory medicine are again very good, but both author and reader have by now lost some of their *élan*. When the book comes to a second edition, it would benefit by a drastic curtailment of the intermediate dull patch, and also by the elimination of the many asides and appendices giving the view of the author on topical subjects, which, however important, are not history. If this were done, the book would certainly become a classic in the literature of medical education.

**The Quicksilver Doctor. The Life and Times of Thomas Dover, Physician and Adventurer.** By Kenneth Dewhurst. (Pp. ix + 192; illustrated. 21s.) Bristol: John Wright & Sons Ltd. 1957.

The picturesque and belligerent personality and the colourful life of Thomas Dover have formed the subject of many articles, including one by Sir William Osler. The first full-length biography in book form, by a distinguished novelist, Mr. L. A. G. Strong, appeared in 1955. This new biography by a medical writer is elegantly and entertainingly written, is fully documented with footnotes, quotations from chronicles, diaries, manuscripts, and other sources, and contains much new material. The story is skilfully presented against the background of the times: the state of medical practice; the quack and his nostrums; such great contemporary figures as Richard Mead (and his indecorous scuffle with John Woodward in the courtyard of the College of Physicians), Sir Samuel Garth, John Radcliffe, Sir Hans Sloane, Barton Booth the tragedian, John Freind. In the chapter entitled "Birth of a Legend", the author takes pains to explain that the famous expedition to the South Seas which Dover helped to finance and in which he played a leading rôle, "was in no sense a buccaneering adventure or a piratical cruise", and he accuses other writers of having distorted this aspect of Dover's career. "Dover's powder", a household remedy for two centuries that has survived in modified form to-day, was first mentioned in his book bearing the grandiloquent title "The Ancient Physician's Legacy to his Country, being what he has collected in Forty-Nine Years' Practice . . ." (1732). Its pages are liberally spiced with bizarre details of his travels and flavoured with anecdotes of doubtful authenticity. There is a good description of the iliac passion (appendicitis), for which oral quicksilver and purging are recommended, and one "revolting prescription" for asthma. Other chapters in Dr. Dewhurst's book deal with "The Rescue of Selkirk (Robinson Crusoe)", "The Quicksilver Doctor", and "Dr. Dover and his Critics". The volume concludes with an 8-page bibliography of manuscripts in the Public Records Office, the House of Lords, the British Museum, the Bodleian Library, &c., and of books and articles.

**The Clinical Management of Varicose Veins.** By David Woolfolk Barrow, M.D. (Pp. xiii + 169; illustrated. 45s.) London: Cassell & Co., Ltd. 1957

Varicose veins and their complications are so common that it is to be expected that many books would be written about them. The fact that this book has gone into a second edition suggests that it has been found useful. The preface does not state for whom it is intended but it seems to be most suitable for those who are training to become surgeons. After a short historical introduction, the relevant anatomy and physiology are described and clearly illustrated. With them there is an account of the ætiology of the condition. The chapter on pathology deals only with the changes occurring in the veins and does not mention the complicating abnormalities which may occur in the skin. After an account of the examination of the patient, there are four chapters on treatment. The last three chapters deal with complications, thrombophlebitis, and prophylaxis and after-care. The bibliography occupies eight pages but, surprisingly, Martorell and Anning are both omitted. There is a good index. Except for the chapter on complications this is an excellent book. The treatment described is orthodox and is set out very clearly with many helpful diagrams but the author should have obtained the help of a dermatologist in writing the chapter on complications. The mythical condition, varicose eczema, is described but with no idea suggested as to why or how it occurs. Bisgaard's treatment for the ulcerated leg is not mentioned. There are many photographs, most but not all of which are good. It can be recommended to young surgeons with the warning that they should ignore the section relating to the skin.

**British National Formulary 1957.** (Pp. 226. 6s. 6d.) London: The British Medical Association and The Pharmaceutical Press 1957.

The fourth edition of this useful, conveniently sized and inexpensive manual, prepared by the Joint Formulary Committee representing the medical and pharmaceutical professions, contains the word "British" in its title, to distinguish it from the U.S.A. National Formulary. Additions, deletions, and amendments are listed on pages 8–10. The section on poisoning in "Notes for Prescribers" includes a monograph on agricultural poisoning, and a note on drug addiction has been added. We are glad to see that "tonics" have been retained. The Formulary itself consists of three sections: general, infants' (on pink paper), and dental practitioners'. An appendix lists proprietary preparations. It is emphasized that a doctor is free to prescribe what he considers to be in the best interests of his patient, whether or not the preparation appears in the British National Formulary. The comprehensive index (22 pp.) is a model. Interleaved copies of this book can be obtained at 10s.

## A New Method of Demonstrating the Retention of Foodstuffs in the Mouth, with Special Reference to Different Forms of Sweets

By ALEXANDER B. MACGREGOR, M.A., M.D., B.Chir., M.R.C.S., L.R.C.P., F.D.S. R.C.S.

*Professor of Dental Surgery and Director of Dental Studies, University of Birmingham, England*

### FOREWORD

THE relationship between the consumption of carbohydrates, particularly refined sugars, and the dental caries rate has been stressed for many years and a great deal of work has been done on the subject, e.g. Toverud (1949), Sognnaes (1949), &c. The work of Stones and his collaborators (1955), however, indicates that merely adding sugar to the diet may not, of itself, increase the caries rate. A careful review of the literature suggests that the quantity of carbohydrate may not be as important as the form in which it is taken. Thus, Bibby, Goldberg and Chen (1951), estimating the amount of sugar in the rinsing fluid after spraying the mouth, showed a very considerable difference in the retention time in the mouth of different forms of carbohydrate. More recently Lundqvist (1952), after showing that a high sugar concentration in the saliva associated with delayed clearance time is associated with greater caries activity, came to the conclusion that candies, particularly toffees and caramels, not only gave a delayed sugar clearance from the mouth but were also associated with a very high caries rate in clinical experiments.

The amount spent on sweets in this country amounts to approximately two hundred and thirty-five million pounds each year (£255 millions 1956), and the average consumption per head of population is 8 oz. a week. This rate of consumption is the highest in the world and should be compared with an average consumption per week of 5 oz. in the United States and Australia, 4 oz. in Canada, slightly over 3 oz. in Sweden and 3 oz. in France.

A possible association of this consumption of sweets, particularly toffees, with a high caries rate, has been suggested, though on somewhat nebulous grounds, for many years. It was, in consequence, thought by the author that it would be of interest if an experimental method could be found by which differing times of retention of varying forms of confectionery and foodstuffs could be demonstrated.

### EXPERIMENTAL TECHNIQUE

Many substances were tried as "indicators" but the choice was somewhat limited owing to certain prerequisites. These were:

(1) Freedom from any toxicity.
(2) Insolubility in water or saliva to obviate possible errors due to diffusion.
(3) Small particle size.
(4) Easy recognition both macroscopically and microscopically.
(5) Stability to withstand destruction during any processes involved in the manufacture of foodstuffs and incorporation of the indicator, e.g. boiling.

Iron oxide powder was tried in the first instance but while this could be used on teeth to be extracted it was unsuitable for use in tracing foodstuffs round the standing teeth as the potassium ferrocyanide used to reveal the iron by the Prussian blue reaction could not be used in the mouth owing to its poisonous nature. The use of iron oxide powder gave encouragement, in that foodstuffs could be traced in fissures, for example; but apart from the major drawback already mentioned, other sources of error were soon found such as iron being already present from medicine or other sources, and also the occasional presence

of iron in the dentine immediately in advance of softening due to caries, where present. The presence of iron in this position although not germane to the experiments under discussion is of considerable interest, and further work is being done to try to elucidate the reasons for its presence.

Aniline dyes were discarded owing to toxicity. X-ray opaque materials were insufficiently accurate for checking disposition, and diatomaceous earth proved unsuccessful owing to the characteristic shape of the diatoms being lost after boiling. Dyes used for the colouring of foodstuffs were tried, but even the reputedly least soluble of these showed sufficient solubility to vitiate the results. After much experimental work along these and other lines an approach was made to the technical division of Imperial Chemical Industries who most kindly supplied, after further experimentation, a suitable dye in the form of specially purified copper phthalocyanin. This dye is pharmacologically inert, completely insoluble in water, is of fine particle size and bright blue in colour.

In the first instance it was decided to work with three different but typical forms of sweetmeat, e.g. boiled sweets, chocolate and toffee. Early experiments in trying to incorporate dyestuffs in home-made toffees in the laboratory, merely revealed the self-evident fact that we lacked both the skill and the knowledge to indulge successfully in the refinements of the manufacture of confectionery. A very large firm of confectionery manufacturers was, in consequence, approached, and their most generous and valuable co-operation is warmly appreciated. Toffees, chocolates and boiled sweets containing the dyestuff have been made for us whenever required, and without this very great help the work would not have been possible.

The experimental work has been divided into two phases, in the first of which dental students were asked to chew toffees, chocolates, and boiled sweets on different occasions and photographs were taken at selected intervals. In addition, a cinematographic film has been taken to record the results.

In the second phase, patients about to have a tooth extracted in the premolar or molar areas chewed a toffee over this tooth before the tooth was extracted. Care was taken to see that these teeth were not grossly carious and as far as possible those showing no caries or only very small carious lesions were selected.

## Results

In the first phase in a random sample of 20 subjects, toffee was seen adhering round fissures interstitially, and cervically, in the area where toffee was chewed in large amounts easily capable of photographic recording five minutes after finishing the toffee (Fig. 1). After twenty minutes this toffee was still present and still in quantities capable of photographic recording, particularly interstitially and cervically (Fig. 2). One hour after the toffee had been consumed it was still possible to record the toffee photographically in many mouths (Fig. 3) but even if not capable of good photographic recording it was easily visible on careful inspection in 17 of the subjects.

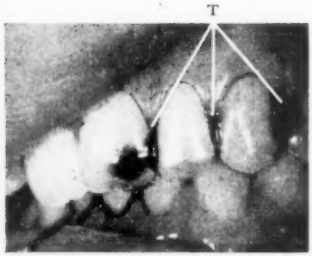

Fig. 1.—Mouth five minutes after chewing toffee.

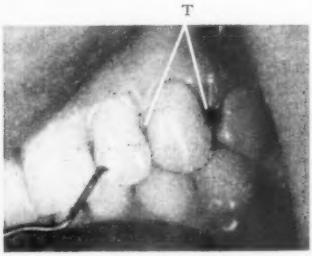

Fig. 2. — Same mouth twenty minutes after chewing toffee.

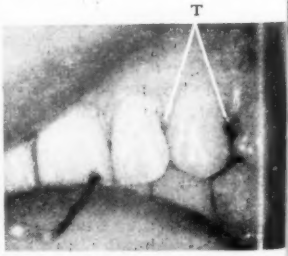

Fig. 3.—Same mouth sixty minutes after chewing toffee. T = toffee in each case. N.B.—More toffee was stuck between and around the posterior teeth but the anterior teeth were chosen for photographic convenience.

These results refer to toffee that could be seen and photographed, or seen, i.e. to toffee present on the surface. It is reasonable to suppose that where toffee could be seen, far more was probably present unseen between the teeth and in many instances where it was not seen there was, in fact, some present interstitially or in fissures and cavities.

A similar method has been used with copper phthalocyanin dye contained in milk

chocolate and boiled sweets, the chocolate and boiled sweets containing approximately the same concentration (1%) of phthalocyanin dye as was present in the toffees. While the distribution in the mouth after chewing appeared very much the same with all three materials, a great difference was found in the *time* of retention of toffees compared with both chocolate and boiled sweets. A few minutes after chewing the appearance of the teeth was very similar with chocolate and toffee, though the amount of chocolate seen interstitially was not so great as when toffee was used. Boiled sweets gave a similar distribution picture, but the amount adhering was not so great as in the case of the chocolate and far less than that seen with the toffee. Twenty minutes after chewing a very great difference was revealed. In only 5 of the 20 subjects slight traces of chocolate containing the dye were seen and a very slight trace only, seen in 2 subjects after boiled sweets. The amounts present were not capable of photographic recording and were not comparable with the amounts seen after toffee. One hour after chewing one subject showed a slight trace of chocolate revealed by the dye but no subject showed any trace of boiled sweets at this time. There was in fact a marked contrast between the appearance seen after toffee one hour after chewing and the appearance seen either after chocolate or boiled sweets.

In the second phase extracted teeth over which toffee had been chewed when still *in situ* were firstly examined by reflected light with a dissecting microscope. An interesting pattern of toffee was frequently revealed outlining the fissures and extending down into them (Fig. 4). These teeth were then split along the fissures and again examined with a dissecting microscope. Ground sections were then prepared, care being taken to see that the direction of rotation of the wheel was away from the bottom of the fissure to guard against the possibility of any loose stained toffee material being forced into the fissure by the grinding process. A typical section of such a tooth is shown in Figs. 5 and 6 from which it can be seen how deeply traces of toffee can be found in these fissures. It was of interest that in many instances where small interstitial cavities were present the toffee had been forced into these cavities after being squeezed between the teeth (Fig. 7) and traces of toffee were even found in shallow cervical cavities (Fig. 8).

To control the possibility that the presence of blue dye was not necessarily associated with the presence of toffee, sample scrapings were taken from subjects in the Phase I experiments and tested for sugar. Even in those subjects where the dyestuff was present one hour after chewing, the dye was found to be associated with sugar when tested by the rapid furfural method. A further possibility that sugar was already present between the teeth before chewing was eliminated by taking samples of food debris from interstitial areas between the premolar and molar teeth and testing them for the presence of sugar. It was of interest in this connexion that one subject who was tested at 3 p.m. gave positive results. After questioning it was found that one hour and a half before, he had finished his lunch by eating a bar of confectionery made of stiff caramel toffee covered with chocolate.

AUTHOR'S NOTE.—For reasons of cost the original colour photographs cannot here be reproduced. Black and white prints failed to differentiate the blue toffee from other dark tones, and by the kindness of the Editors the present compromise has been reached. The somewhat artificial appearance of the illustrations is due to blue ink having been applied to the black and white prints. The position and extent of this blue ink does, however, correspond to the position and extent of the blue coloration in the original colour photographs.

A. B. MACG.

## DISCUSSION

The work done so far is insufficient to allow final conclusions to be reached. Further work is continuing on more subjects and with the use of different types of confectionery and foodstuffs.

Certain conclusions can, however, be drawn from the work so far done.

(1) The incorporation of blue copper phthalocyanin dye in foodstuffs offers a method by which the disposition of foods in relation to teeth can be tested. It is sufficiently stable and colourful to allow photographic reproduction of both macroscopic and microscopic results.

(2) It would appear from the results so far obtained that chewing of toffee results in very considerable quantities being retained in and around the teeth for considerable periods, in many instances over one hour after chewing.

(3) There appears to be a very considerable difference in both the quantity and time of retention between toffee on the one hand, and chocolate and boiled sweets on the other.

(4) The chewing of a toffee results in many instances in parts of it being forced into the

fissures, even when these are small, and it seems probable, especially in view of the experiments in Phase I, that rapid dissolution and removal from such sites as these fissures is unlikely. The presence of the toffee in small interstitial cavities and even in cervical ones is also noteworthy.

These results assume particular significance in view of the known rapidity with which sugar solutions in the mouth can produce acid. They also are in marked agreement with the results given by Lundqvist for the Vipeholm experiments, in which it was shown that both the caries incidence and the sugar clearance time from the mouth, particularly the former were far higher for toffees and caramels than for the other foodstuffs and sweets given to children during the experiment (Figs. 9, 10).

## The Problem of Noise in the Royal Air Force

By Wing Commander P. F. KING, F.R.C.S.Ed., D.L.O., and
Flight Lieutenant R. P. GANNON, B.Sc., M.B., Ch.B.

*Department of Otorhinolaryngology, and R.A.F. Acoustics Laboratory, Central Medical Establishment, Royal Air Force*

### INTRODUCTION

IN the Royal Air Force, as in the other Services, and indeed in industry, noise is a problem which has to be tackled principally because of its effects on personnel. In this paper, the problem of noise in the Royal Air Force will be discussed with an eye on circumstances which are largely peculiar to the Royal Air Force; the damaging effects of artillery noise will not be included, as the noise hazard from arms of all calibres is a problem which is common to all three Services. Broadly speaking, exposure to noise for any length of time will produce both fatigue in the individual with lessened work efficiency, and fatigue of the organ of hearing. Finally, if the insult is repeated often enough and for long enough, auditory fatigue will become converted into persistent perceptive deafness. The production of perceptive deafness in boilermakers was described in the middle of last century, but it was known long before that exposure to noise produced deafness under certain circumstances.

We propose to deal principally with the noise of aircraft engines and the effect of this noise on people in different situations, but we shall also consider ancillary equipment in the same light. Experience has shown that with the constant search for more advanced aircraft, of higher ceiling and greater speed, the power of the engine has increased and with it the noise output.

### NOISE MEASUREMENT—ANALYSIS—ASSESSMENT

Noise measurements are made in order to assess the risk to hearing. The difference between the noise level measured and that believed to be safe is the noise reduction required. The subjective effect of a noise depends on its frequency composition, different frequencies having different effects, certain frequency ranges being heard more easily than others. Other frequency ranges, not necessarily the same, are more damaging to the hearing. The relationship between noise level, frequency, and duration and the resultant effect is extremely complicated so that instruments are not available to give a single figure for the subjective effect of a noise. Instead we measure the total sound level, the variation of level with frequency, and the duration. In practice the sound is divided into frequency bands and the graph of variation of level with frequency is known as a frequency analysis. The subjective effects may then be assessed from these results.

Noise levels are usually quoted in decibels, sound pressure level and the decibel is a LOGARITHMIC measure of the RATIO of the POWER of the sound measured to that of some standard sound level. The subjective effect of noise is more akin to this logarithmic scale than to a linear one.

Typical noise levels are:

| | |
|---|---|
| Near jet aircraft at full power .. | 130 db. s.p.l. |
| Underground railway .. .. | 100 db. s.p.l. |
| Conversation .. .. .. | 65 db. s.p.l. |

From the results of the noise measurement an assessment of the noise hazard may be made.

## Noise Hazard: Assessment of Risk

The assessment of the risk of permanent hearing loss from noise has been studied by many workers, in many fields. There remains, as yet, no definite agreement on what constitutes dangerous noise and any assessment is to some degree a matter of conjecture and personal opinion. However, the weight of experimental evidence required to give a definite answer is gradually being accumulated, but the very nature of the task makes this a prolonged study.

Kryter (1950) concluded from his own studies and those of other workers that the maximum safe intensity at which no deafening effect will occur is probably in the neighbourhood of 85 db. s.p.l. per critical band for long periods of exposure applied intermittently over months or years. He suggested that, for brief exposures lasting up to one hour, the level could be raised to 100 db. per critical band. He also made it quite clear that *a noise must be analysed before its deafening value can be estimated.*

Parrack (1951) proposed a deafness risk criterion, which showed that he considered the safe level to be 95 db./octave band or less for a wide range of frequencies. Slightly higher levels were allowed at the very low frequencies.

Rosenblith *et al.* (1953) in a comprehensive study of the problem of noise and man defined what they termed the "damage risk criterion", not only in terms of frequency and intensity, but also of exposure time and character of the noise under consideration. This criterion was adopted later in 1953 by the Benox Group (1953) as their reference standard and has since found wide acceptance. It is shown in Fig. 1. It was put forward

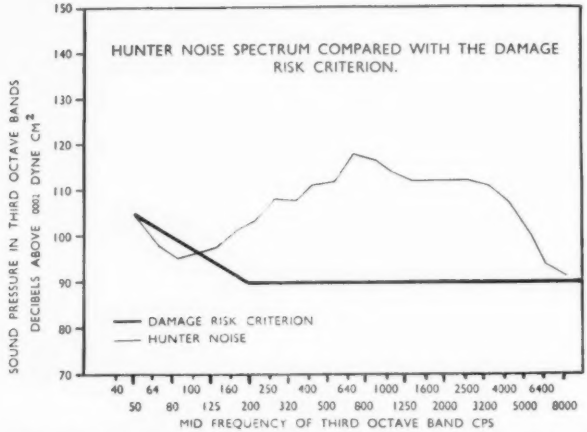

Fig. 1.—The noise spectrum of a Hawker Hunter Fighter compared with the "damage risk criterion" of Rosenblith *et al.* (1953).

with qualifications defining the character, duration, and intensity of the noise—but is considered to be safe for a working lifetime of exposure.

A more recent study of the damaging effect of noise was made by the Exploratory Subcommittee Z24-X-2 of the American Standards Association in their report published in 1954. This implies a criterion lower than that proposed by Rosenblith and his colleagues, but which is not so general in its application and has not received such wide acceptance. It cannot be applied in the assessment of aircraft noise—as the frequency analyses of the noise do not lie within the limits on which the criterion is based.

The noise under consideration is therefore measured, recorded and analysed, and data recorded about exposure time and character of the noise. This analysis is then compared graphically with the damage risk criterion as in Fig. 1. This shows to what extent the noise constitutes a danger to hearing. In the final assessment of the risk, allowance is made for exposure duration if shorter than that quoted. In this way we attempt to assess the risk of deafness for men working in noise.

## The Aeroplane and Aircrews

When one considers the crew in an aircraft, it will be appreciated that they are situated in a noise field of greater or lesser intensity, depending on the type of aircraft, and that

they will be exposed to noise for varying lengths of time, depending on the operational role. For example, jet fighter pilots fly in a relatively quiet environment for short periods, whereas transport and maritime reconnaissance crews fly for considerably longer periods in noisier aircraft. The effects of noise can be divided into short- and long-term effects; the short-term effects are: Interference with communication in flight between members of the crew, or interference with communication over the radio telephone. To this is allied general fatigue, partially induced by noise. Fatigue of the organ of hearing, producing partial hearing loss in flight is by no means uncommon in crews of Shackleton aircraft (Dickson *et al.*, 1953) but, in most cases, the hearing will recover after an adequate rest on the ground. Continued acoustic insult and lack or misuse of protective equipment will perpetuate fatigue into a lasting deafness—the principal long-term effect.

Different measures can be adopted to overcome this, for example:

(*a*) Careful selection of men for aircrew duty. Every effort is made by means of clinical and audiometric testing to ensure that men engaged for aircrew duty have no hearing loss before commencing training, and those with histories suggestive of susceptibility to noise are also excluded. We have not yet been able to devise a practical and easily worked noise-susceptibility test which could be applied to all entries for air or ground service.

FIG. 2.—Cotton flying helmet incorporating the standard R.A.F. earmuff, fitted with telephone receiver.

(*b*) The periodic examination of aircrew, both clinically and by audiometry, is extremely valuable, particularly of those men who show themselves to be susceptible to noise.

(*c*) Examination of the noise itself in the working situation, is of first importance and leads to constructive suggestions both in the shape of protective gear for the men and also such measures as sound insulation of the cabin. This has been done in Shackleton aircraft with a certain amount of success and similar surveys have been done in the Beverley transport aircraft and in the Whirlwind helicopter, where it is hoped that a similar degree of success will be achieved.

(*d*) Further measures may be taken to protect the individual himself, for example, the issue and wearing of a Type F flying helmet, which was devised at the Institute of Aviation Medicine, Farnborough. Laboratory examination of this helmet has shown that it is effective in reducing the noise falling on the ears, and in many cases, may reduce the noise below the level where it may be considered a hazard. Experiments have recently been put in hand in which a radio telephone receiver is incorporated in a protective ear muff, which is, in turn, built into a cotton helmet (Fig. 2). With this device we hope to provide effective

protection for crews of transport aircraft and those employed on maritime reconnaissance. Such a helmet will have the existing advantage of the Type F with regard to clarity of reception on the radio telephone, and will provide effective acoustic insulation. The sound damping of the cabin in selected aircraft has already been mentioned.

In practice, it is convenient, in the light of present-day requirements, to consider the likely hazard for aircrew employed on different operational duties. Pilots of jet fighter aircraft are unlikely to be exposed to hazardous noise, except when taxi-ing before take off and after landing, when the cockpit canopy is generally open. The pilot is protected by a Type F flying helmet, the fit and seal of which is ensured by the addition of a protective "bone-dome" or crash helmet. During flight, he is seated well forward of the engine(s) and is operating in a relatively quiet environment.

The situation with regard to present-day bomber crews is much the same, and it should be noted in passing, that the real hazard from engines powering this type of aircraft is to the ground crew who service them. The hazardous effect of noise made itself felt on crews in piston-engined bombers during World War II, when forerunners of the Type F helmet were devised; while as long ago as 1939 the effect of noise on the ears of aircrew was demonstrated by Dickson and Littler.

In Coastal Command, the noise in the cockpit of the Shackleton aircraft has proved a problem and many field surveys have been done, including pre- and post-flight audiometric testing of aircrews in a mobile hearing test chamber, in order that the degree of hearing loss sustained by the ears on an operational flight could be assessed. The present Mark of Shackleton aircraft now has the cabin insulated and, in addition, a small rest room is provided, which lessens the effects of fatigue considerably. In Transport Command, the engines of the Beverley aircraft produce a high intensity noise field, and many complaints have been received from the crews. Following noise analysis, selected aircraft are being sound-insulated.

### The Aeroplane and the Passengers

At the present time, the aircraft used for trooping are the Beverley and the Hastings aircraft, in both of which the noise level in the passenger compartment is relatively high. In the future, when trooping is undertaken by a Comet aircraft, the noise in the passenger compartment will be negligible. The evacuation of casualties is normally undertaken in Hastings aircraft and the provision of ear defenders should be considered in some circumstances.

### The Aeroplane on the Ground

Today, the power of aircraft engines has increased and it would be opportune at this time to mention the types of aircraft engine which are now in use and to compare the noise emanating from them. The first of these is:

(i) The piston engine, which can produce up to 120 db. s.p.l. overall.
(ii) The turbo-prop with a sound pressure level of 120 to 125 db. s.p.l. overall.
(iii) The turbo-jet engine with a noise output of 125 to 133 db. s.p.l. overall.
(iv) The turbo-jet with after-burner has a noise output of up to 150 db. s.p.l. overall.
(v) Rocket motor (assisting jet take-off) up to 150 db. s.p.l. overall.

Fig. 3.—Ground servicing of a Vampire Fighter showing the positions of the ground crew during engine running.

### The Effect of Noise on Ground Personnel and Its Control

It is the ground personnel who are now most exposed to the noise hazard from engines. Regrettably, many men employed in the aircraft engineering trade group do become very used to working in noisy situations. This is probably due, on the one hand, to familiarity with the working conditions, and also, on the other hand, to the insidious onset of deafness. Where the hazard has been explained to these men, and when efficient and effective protective devices have been shown them, such devices have been received with enthusiasm.

Broadly speaking, ground crew are liable to be exposed to hazardous noise in all phases of the aircraft's movement on the ground, namely taxi-ing, take-off and landing. Those employed on first and second line servicing and also those employed in maintenance units on the servicing of engines, are undoubtedly exposed to hazardous noise (Figs. 3 and 4). For

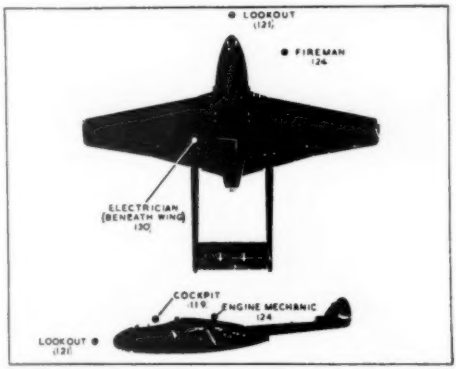

Fig. 4.—A diagram illustrating the position in and around a Vampire aircraft of the ground servicing crew, and the total noise level in their working situation when the engine is running at maximum r.p.m.

those employed on first and second line servicing, the exposure per working day is not, of necessity, great, but, nevertheless, the men need protection; on maintenance units, however, where engines are run on test beds, the hazard is considerably greater and all men working on such sites must be adequately protected.

The problem can be tackled along the following lines:

(*a*) Propaganda disseminated by the Medical Officer and the Senior Technical Officer on the hazardous effects of noise and its consequences. This may also be supplemented by visual instruction and a film is now being made for showing to all ground personnel who are likely to be affected by noise.

(*b*) The periodic check of the hearing of men in exposed situations is necessary, and, allied to this, one must emphasize the desirability of using "individual pure tone" or "group audiometry" before the man starts in employment and at regular intervals during this working life, in order that deterioration in the hearing acuity may be discovered early.

(*c*) Protection for the ears of the individual is an absolute necessity under these circumstances, and, until recently, a small plastic plug was supplied. This was found effective to a certain extent (Dickson *et al.*, 1954*a*), but was not wholly adequate against the damaging effect of high intensity noise from jet engines. As a result, the protective ear muff devised by the National Research Council of Canada was adopted, with certain modifications, and is now in production in this country and being distributed for use by ground crews.

(*d*) The rotation of crews may also be considered, where unprotected or partially protected men are working in very high intensity noise levels for periods which would appear to be hazardous. By this it is quite feasible that, although men would be exposed to high intensity noise, individually they would not be exposed for a period likely to cause permanent damage. This is a technique which may have to be considered for men working on newer forms of propulsive equipment which are now being devised.

(*e*) Mufflers and silencers for engines can be used in an attempt to reduce the noise at source. No wholly effective portable muffler of a type likely to find universal acceptance has been devised as yet and the most effective mufflers are generally those which are static and built in to a muffling pen.

### Effect of Noise on Operations

Noise may have an adverse effect on the conduct of flying operations, principally through interference with communications and the effect of this is likely to be felt in the control tower, the briefing room and some administrative offices. It is our experience that on some airfields the control tower is extremely close to the servicing pans, when the air traffic controllers are exposed, not only to a noise level which makes communication and the reception of verbal signals virtually impossible, but to one which may itself be hazardous to the hearing. It is also within our experience that on some airfields the general administrative offices which control day-to-day life on the station are subject to noise during the time that aircraft are operating from the airfield to an extent that the efficiency of those working in them must suffer. The problem can be tackled on general lines by careful attention to the site and layout of airfields, and to the alteration of the flight pattern, if this is at all possible, in order that affected areas on the airfield may have some relief. Control towers are a problem in themselves and require careful siting and effective sound insulation. The adverse effect of noise on aircrews trying to sleep should not be forgotten.

### Effect of Noise on the Civil Population

It is only on rare occasions that noise falling on a civil population is actually liable to be a hazard to the hearing. The situation of Royal Air Force airfields is such that only relatively small communities are likely to be affected. The annoyance value of noise, however, is one experienced over a relatively wide area surrounding any airfield. It affects particularly those areas related to the servicing pans or to the ends of the runway. Such areas will either have constant annoyance during servicing or, when flying operations are in progress will be intermittently subjected to noise of high intensity, depending on their relation either to the runway or the flight pathway. The problem may be tackled by attempting to reduce the noise at source by the use of silencers, mobile or static mufflers, or by the use of noise muffling pens, and by the alteration of the flight pattern.

Pens have proved of great value at airfields where aircraft are ground tested before flight and delivery. They have the advantage that the noise is contained and the efflux is discharged into a large Cullum muffler. The disadvantage of this equipment is that each type of aircraft requires its own individual pen; for instance, a Hawker-Hunter fighter will not fit into a Gloster-Javelin muffling pen. From the point of view of present operational requirements in the Air Force, it is quite impracticable, therefore, to consider erecting such pens, at heavy cost, when the squadron for whom they are intended might well be moved. It is possible that with the standardization of fighter aircraft equipment during the next few years such an ideal will be realized, when we may have the muffling device for the standard fighter supplied to operational airfields.

The use of deflecting walls has met with only partial success, in that there is no absorption of sound. The noise is deflected, possibly to fall on an area hitherto unaffected. Walls have the further disadvantage with large aircraft that to be effective even locally they must be relatively high.

Probably the most important factor with regard to the alleviation of the annoyance of noise is a good public relations service. This has been well developed in the United States Air Force and every effort is being made within the Royal Air Force on similar lines, whereby responsible persons in civil communities and the community itself are informed of the efforts being made to control the noise; of the difficulty in siting dispersals and in reducing noise at source and of the necessity for maintaining a fully equipped and efficient fighter and bomber force.

It should be mentioned, at this stage, that the muffling of engines in flight is virtually an impossibility. The amount of benefit conferred by such a silencer would be very small in terms of sound reduction, while, at the same time, the efficiency of the engine would be reduced. From an operational point of view this is a technique which cannot be considered; but the noise from aircraft in flight produces problems of its own which can only be tackled by changing the flight pattern and the flight pathways.

### Other Noise Sources

So far we have concentrated entirely on the aircraft engine as being the source of damaging or annoying noise, but mention should also be made of auxiliary equipment used in connexion with aircraft, for example, starter motors and generators. These, particularly if used in an enclosed space, can produce noise levels which would be damaging to the unprotected ear. During repair of aircraft, such procedures as riveting, sand-blasting, metal spraying and vapour blasting may all produce a work situation in which the sound is hazardous and in which the workers require protection.

### The Care of the Deafened

It is pertinent to enquire at this stage into the management of those who have suffered damage to their hearing as a result of exposure to noise. In the first instance they are examined by an otologist to assess the degree of deafness. The individual is then moved away from work in a noisy environment for a period of at least three months. This is followed by re-examination by the otologist to assess the degree of recovery or permanent injury. Where recovery occurs the man is returned to his employment adequately protected, and checked periodically to assess his progress.

When recovery fails to occur the choice lies between re-mustering the man to a trade in which he will not be unduly exposed to noise, or a return to work adequately protected. The latter course is only justified in skilled, highly trained individuals—and must be accompanied by close and regular supervision to detect further deterioration in the hearing. Further hearing loss in such a person will necessitate re-mustering in order to preserve him from severe perceptive deafness, normally associated with persistent and aggravating tinnitus. It must be emphasized that no effort should be spared to save these men from the unhappy lot of irreparable deafness in their later years.

### The Future

The future is shadowed by many problems in this field. With the existing policy pointing to a standard fighter and standard types of bomber, it is possible that development of engines for military use will cease. However, if, as seems more likely, their development continues, to what levels will the noise increase? The use of mobile silencers and mufflers is practically in its infancy and much research is still required to produce an effective muffler for each engine during ground running. Such a mobile muffler will be the answer to many difficulties. The use of rocket missiles introduces many of the problems attendant on the use of artillery, whose role they fulfil. Rocket-powered aircraft will bring similar difficulties in their wake. The use of aircraft employing vertical take-off is still in an experimental stage. Development on these lines is progressing; and while it is possible that the noise initially will be greater, it should be more localized.

Finally, how next do we protect the man? We believe that with the existing ear muff, the Royal Air Force Mark III, we have an adequate defender affording the best degree of protection against existing noise. It is unlikely that any other muff would give more effective protection against greater noise. At first sight, it seems logical to encase the head in a helmet, in an attempt to stop the conduction of high intensity sounds through the bone. The entrance of sound to the body, and its conduction within the body, is a problem which now faces us. On the information which we get from this work, so shall we be able to decide the best means of protecting the individual either by helmet, suit or by an individual cell fitted with remote control. Above all, we must remember the man, who must work while wearing these protective devices.

### Acknowledgments

Before closing, we should recall the work in this field of those who have gone before who have given us a basis on which to approach and tackle the problems created by noise in a modern Air Force.

We wish to thank the Director-General of Medical Services, Royal Air Force, for permission to publish this paper.

## DISCUSSION

**Air Vice-Marshal E. D. D. Dickson:** There can be no doubt that noise of the intensity encountered to-day will give rise to hearing loss. The human ear and human nervous system are limited in their tolerance for noise. Having conceded that noise causes hearing loss it is time we considered certain points in evaluating the damage sustained:

(1) Provision of some sort must be made for calculating the percentage disability of hearing that man might have incurred. What sort of test do we give and how do we calculate from that test the percentage of disability? The aim should be to get a number that could be applied to some schedule award for total disability. We must remember that noise-induced hearing loss is not a total loss of hearing function, it is invariably a partial loss.

(2) Diagnosis in determining what kind of hearing the patient has. To this is closely related the problem of causal relation.

(3) The possibility of recovery of function once noise-induced loss has been produced is an important question. Is it permanent? How long do we have to wait to know whether it is permanent or not?

(4) Lastly we must consider the loss which occurs normally—simply as a result of ageing—presbycusis. What is its relation to the hearing loss that may be induced by noise? Does presbycusis make an individual more liable to noise-induced hearing loss or vice versa?

What we must recognize is that noise-induced hearing loss exists and can be related statistically to some factors of noise. These have been stated to include intensity, spectrum and length of time the individual spends in noise. The element of susceptibility has not been sufficiently investigated; it is perhaps opportune to embark on some research project to obtain some clear-cut information.

I want to stress again the importance of pre-employment examination by pure-tone audiometry of all those about to embark on a noisy occupation. But to be of any value it must be carried out under standard and controlled conditions by individuals conversant with the application of the test. Only by periodical surveys will we be able to determine who are the individuals most susceptible to noise—and also the effects of noise in aggravating any pre-existing hearing loss.

In the final assessment of noise-induced hearing loss we must recognize that the ability to hear and understand everyday speech is what we are really interested in when we formulate a percentage figure in hearing loss, and the means for assessing it.

Speech is the thing that is really important about the sense of hearing. We are dealing with the function of receiving speech, the receiving of auditory communication. It is not an anatomical proposition dealing with extremes of hearing either extremely high or extremely low tones or even the very greatest degree of sensitivity, but it is the ability to receive speech. This puts certain limits on the frequency range in which we are interested and means that certain parts of the frequency range are more important than others. If we accept this general principle we at least have a foundation from which we can start in an attempt to assess the disability incurred by exposure to intense noise. We cannot propound a concept of hearing loss due to noise without some means of assessing its effects on social adequacy.

**Surgeon Captain C. N. H. Joynt** enquired whether ear, nose and throat specialists in the Royal Air Force encountered much clinical deafness due to high intensity noise generated by aircraft in the course of their normal practice. He had not encountered many cases over a good many years as an otologist in the Royal Navy and this was also the current experience of ear, nose and throat specialists at Naval Hospitals whose experience on this point had recently been ascertained.

**Wing Commander King,** in reply, said there was no doubt that the time was coming when the disability resulting from deafness would be the subject of a new assessment and that many of the factors mentioned by Air Vice-Marshal Dickson would have to be taken into account.

In reply to Surgeon Captain Joynt's query he said that a full survey was being instituted to obtain further information on this aspect of the problem. It was not the practice in the Royal Air Force to invalid deaf personnel, if this could be avoided, but rather to employ them on other duties where they would not be exposed to further risk of cochlear damage. He pointed out that, on account of the more dramatic onset, a man was much more likely to report deafness resulting from gun-fire than from repeated exposure to the noise of jet aircraft, of which, because of its gradual onset, he might be unaware.

**Spot Diagnosis.** Volume 3. Compiled by the Editors of the *British Journal of Clinical Practice.* (Pp. 140; illustrated; 10s. 6d.) Harvey & Blythe Ltd. 1957.

The art of spotting a diagnosis from a photograph and one or two verbal clues bears as little relation to bedside diagnosis as does the solving of a crossword puzzle to the understanding of an obscure book. All the same it is an entertaining activity and helpful in passing examinations.

This, the third volume of Spot Diagnosis, contains photographs of more than a hundred cases which the reader, or rather the viewer, is asked to solve. The standard of the material is very patchy. Some pictures are quite unfair and I doubt if one in a hundred clinicians could spot the clues in Fig. 6 or the diagnosis in Cases 32, 87 and 88. Case 89—the drawing of a eunuchoid is very poor and a good photograph is needed instead. Yet, on the whole the photographs are well taken and reproduced and the letterpress mainly accurate, and the book will provide diverting snippets of clinical knowledge varying from trivial museum oddities to commonplace clinical essentials.

**Sir George Buckston Browne.** By Jessie Dobson, B.A., M.Sc., and Sir Cecil Wakeley, Bt., K.B.E., C.B., LL.D., D.Sc., F.R.C.S., F.R.A.C.S., F.A.C.S. (Pp. viii + 143. illustrated. 25s.) Edinburgh and London: E. & S. Livingstone. 1957.

The story of the life of Sir George Buckston Browne is interesting, not only for the success-story it depicts but because it gives an extraordinarily vivid insight into an important transition period in surgical history, that is, between 1875 and 1900. The names of the authors are a guarantee of literary finish, and the publishers have produced the book in delightful fashion. Sir Harry Platt has written a foreword.

Those who are interested in genealogy can feast themselves on chapter one, in which the family-line is traced back to the sixteenth century. (We detected one wrong date on page 2). The main part of the book contains large and well chosen extracts from the autobiography which Sir George began when he was over 90 years of age. Sir Hugh Lett has written an appreciation of Sir George as a surgeon.

George Buckston Browne was the eldest child of Henry Browne, a physician on the staff of the Manchester Royal Infirmary. The father was evangelically-minded, but puritanical views and practices did not appeal to the son who commented "My father and I were the very opposite. We never had a thing or a thought in common". Nevertheless when George wished to seek his fortune in London, his father allowed him £160 a year to study medicine at University College Hospital. He was a successful student, strong-minded, impetuous, independent, business-like, and very ambitious. Thinking he had been unfairly treated in the Final F.R.C.S., he refused to enter again for the examination. He was house-surgeon to Erichsen and qualified in 1874. He became demonstrator of anatomy, and then, suddenly, fortune favoured him. Sir Henry Thompson had noted Browne's ability as house-surgeon, and, being in need of an assistant, asked Browne to work with him. Thompson at that time had the biggest genito-urinary practice in England and probably in Europe. He was accustomed to take three months' holiday in the year and left a great deal of responsible work in the hands of any assistant he could implicitly trust. Browne was very capable and conscientious and, after an initial difficult period of getting used to Thompson's peculiarities, served him faithfully for fourteen years. He became as skilful as, or more skilful than, his master and when, in 1888 he severed his connexion with Thompson he virtually took the premier place in that line of practice in London. Assisted and encouraged by a devoted wife he worked seven days a week for twenty-five years without taking a holiday. He maintained his health by taking long walks in the country around London. Only when he had become wealthy did he begin to take long holidays and to indulge his artistic leanings. Like Thompson, Buckston Browne had strong views on diet, and again like his master he found he was much better in health when he gave up drinking beer, wine and spirits. Curiously enough his example induced his own father to become a teetotaller, so in that at least they had something in common.

After the loss of his wife and only son Buckston Browne used his fortune to benefit worthy causes. The Harveian Society, University College, and particularly the Royal College of Surgeons were the objects of his bountiful generosity. His purchase and endowment of Down House and the establishment of the Buckston Browne Research Farm were among his munificent gifts. In 1926 he was elected a Fellow of the Royal College of Surgeons and in 1931 he was knighted. He died at the age of 94 in 1945. He preserved his faculties to the end and walked long distances when he was over 90. He once visited his fellow nonagenarian in Wimpole Street, Sir Thomas Barlow, and when leaving, his friend wished to call a cab. "No, thank you", said Sir George, "I am only going to Waterloo and shall walk." A wonderful man and a princely donor.

**Coronary Heart Disease, Angina Pectoris, Myocardial Infarction.** By Milton Plotz, M.D., F.A.C.P. (Pp. x + 353; illustrated. 90s.) London: Cassell & Co. Ltd. 1957.

Increased interest in coronary arterial disease in recent years has sprung from increased proficiency in its electrocardiographic diagnosis, and from a wider hope that the cause of atherosclerosis may yield to researches into the metabolism of fats, and that even its prevention may some time be realized. The author of this monograph refuses to accept the disease as the natural outcome of senescence, but impatiently probes the probable part played by multiple factors in its causation, enunciating impartially the opinions of others on this issue, as well as giving his own. This inevitably leads him to discuss controversial matters like the effect of smoking, diet, and anticoagulant or other drugs, on the health of the coronary arteries. All this he has done in a commendable way, for he has written clearly, concisely, and authoritatively on his subject, and has added a comprehensive bibliography to each of his chapters. He deals successively and succinctly with the response of the coronary circulation to disease affecting it or its environment, clinical presentation of coronary arterial disease, its electrocardiographic diagnosis, prognosis, and treatment. The author is emboldened to write on preventive and on surgical treatment, and concludes with a useful chapter on its medico-legal aspects.

No doctor interested in coronary arterial disease—and no doctor can be without this interest—should fail to possess this help to understand it.

**Extensile Exposure.** By Arnold K. Henry, M.B.Dublin, M.Ch.Hon., Trinity College, Dublin and Cairo, F.R.C.S.I., Chevalier de la Légion d'Honneur. 2nd edit. (Pp. xii + 320; illustrated. 45s.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

There cannot be a surgeon, certainly an orthopædic surgeon, who is unfamiliar with the first edition of this book in which Professor Henry, in his inimitable style, taught him the first necessity of his craft—to get safely and quickly to bone. The second edition is nearly twice as long. It includes all the material of the first, for the most part unchanged. The new pages are devoted to the extensile exposure of the vertebral artery and the posterior cervical rami, the posterior approach to the stellate ganglion and the left subclavian artery, the anterior approach to upper thoracic ganglia and the pulmonary artery, and the extraperitoneal exposure of the vessels and nerves of the pelvis through a mid-line incision. Also included is an ingenious method of dividing all the sensory nerves of the hip-joint through anterior incisions.

All this material, much of which has been published before in a variety of journals, is presented in the unique style that we have come to expect from one of the world's greatest teachers of surgical anatomy—accurate, vivid and written so attractively as to merit inclusion even in the bedside library. But valuable as it is to have these papers collected under one cover, it is impossible, even though a little churlish, not to regret the demise of the first edition, a gem, unique amongst surgical monographs. The new edition is too much of a hotch-potch of unrelated material to win quite the same place in one's affection.

**Mental Deficiency.** By L. T. Hilliard, M.A., M.B., D.P.M., and Brian H. Kirman, M.D., D.P.M. (Pp. xvi + 517; illustrated. 60s.) London: Churchill. 1957.

This book is largely the work of the staff of the Fountain Hospital, with some assistance from a Medical Research Council team. The hospital cares largely for young low-grade defectives and provides what many would regard as a perfect setting for clinical inertness and a rather drab form of custodial care. How wrong such a concept would be, is very vividly shown in this book. Dr. L. T. Hilliard and his friends have not simply followed the design and text of other books, but have set out boldly to describe in their own way the social, pathological and clinical aspects of mental deficiency. They have not hesitated to attack—for example in the section on cretinism—things which in their own extensive experience, they believe to be misconceptions. They have also described in a most readable way details of the law as it applies to defectives, and the social arrangements made for them outside hospitals.

The result is a textbook which is clear and comprehensive, and is probably well ahead of anything now available in English. It is beautifully produced and well illustrated. The two principal authors have left the writing of the pathology section to a neuropathologist, Dr. L. Chrome; and the psychology section has been written by Dr. J. Tizard and Dr. N. O'Connor. The separation of pathology and clinical accounts is sometimes mildly inconvenient perhaps, but cross references are plentiful and the index is full. The book deserves a wide circulation among doctors, medical students, and lay workers in mental deficiency.

[*Continued on p.* 55

**The Physiology of Nerve Cells.** By John Carew Eccles. (Pp. xii + 270; illustrated. $5.75.) Baltimore: The Johns Hopkins Press. Distributed in Great Britain by the Oxford University Press. 1957.

The investigation and analysis of the electrical activity of the nervous system has been dependent upon accurate methods of magnification and recording of minute changes of electrical potentials lasting for periods as brief as 0·1 m.sec. The application to these problems in the last twenty-five years of thermionic valve amplifiers and cathode-ray oscillographs opened up a wide field for research, of which full advantage has been taken. In the last five years or so, the need to narrow down the observations to the changes occurring in a single neuron has been made possible by the micro-electrode. The cell with its axon and dendrites and its surrounding multitude of synaptic knobs remains in situ, while its individual activities can be recorded as though it were isolated. The tip of a micro-electrode has a diameter of from 0·5 $\mu$ to 1·0 $\mu$, and by a micro-manipulator it can be passed through the wall of the cell so as to rest within its substance. Penetration of the cell is recognized by the special characteristics of its electrical record. Complementary to this technique has been the histological study of the cell and the synaptic knobs with the electron microscope. The great magnification has made possible measurements of the size of the knobs, and of the synaptic clefts which separate them from the cell-membrane; such measurements have been valuable in the understanding of the physics of synaptic transmission and have corroborated conclusions drawn from the studies of electrical activity at this site.

In this engrossing book, Professor Eccles has gathered together the observations of his own department of research, and those of others in this field. He has improved the micro-electrode still further, by making it twin-barrelled. By this means the cell can be subjected to a change of its resting potential, or to a variation of its ionic composition, and the effects on its electrical characteristics recorded during the passage of nervous impulses. A wide variety of experiment and of careful measurement has resulted in the definition of the electrical properties of the cell membrane, of synaptic activity and of the cell discharge which is propagated down the axon as an impulse. For the first time, it has been possible to demonstrate graphically, and to explain satisfactorily in electrical terms, the process of inhibition of the discharge of a cell by synaptic activity, Much is now known of the physical characteristics of synaptic transmitter substances, but the identification of these substances within the C.N.S. has failed, with one exception. Acetylcholine has been shown to be responsible at the synapse for exciting the Renshaw cells (situated in the ventro-medial part of the anterior horn of the spinal cord) which exert an inhibitory action on the motoneurones of the same segment. In the last part of his book, Professor Eccles comments on "aspects of functional architecture of the C.N.S." He suggests that there are basically two types of nerve-cells, excitatory and inhibitory All inhibitory action has been observed so far to be exerted by short-axon interneurones only, and he postulates that long pathways are formed by axons of excitatory cells, and inhibitory cells are short-axon neurones lying in grey matter. In the serial links of neuronal pathways, the question is asked whether there is a regular alternation in the nature of the transmitter substance employed. Although the latency of action of all synapses is about the same, the duration of the synaptic activity varies considerably; this could be explained if a barrier existed around certain synaptic clefts, preventing the diffusion of the transmitter substance.

The information brought together in this book is concentrated, and the reviewer found it necessary to revise his scanty knowledge of physics in order to appreciate the elegance of the experiments and the significance of the findings. But the effort is well worth while, in order to keep abreast of this fascinating field of work. Such fundamental knowledge concerning the units of the C.N.S. will ultimately have far-reaching effects, both in the understanding of disorders of neural function and in treatment.

**Principles of Epidemiology.** By Ian Taylor, M.D., M.R.C.P., D.P.H., and John Knowelden, M.D., D.P.H. (Pp. vii + 300; illustrated. 30s.) London: J. & A. Churchill Ltd. 1957.

A book on the principles of epidemiology is welcome as it is over twenty-five years since publication of the last comparable work on the subject. Students and practitioners of public health and preventive medicine, and the increasing number of others who now find it useful to employ epidemiological methods in their inquiries, will study it with interest. They will find a book with many virtues, though some may be disappointed that the emphasis is so heavily upon infectious disease.

The first four chapters are devoted to sources of epidemiological information and to a

fairly detailed description of simple statistical methods used in its analysis. Assessment of results is discussed briefly but no reference is made to the use or abuse of tests of significance. Subsequent sections deal with agents of infection, modes of transmission and the consideration of those characteristics of man and his environment which influence the pattern of disease in the community. The problem of how much statistics and microbiology to include in a book of this kind is a difficult one that the authors have resolved reasonably well; only those aspects of these subjects that are essential to the study of epidemiology have been included. No attempt is made to describe the epidemiology of individual diseases but principles are abundantly illustrated by practical examples, mostly of topical interest. References, given as footnotes, are well chosen and just sufficient in number to allow the more important arguments to be studied further. Considerable care has been taken over the accuracy of information that is presented and there is little evidence of personal bias in the discussion of controversial matters.

This book should prove a useful introduction to the principles of epidemiology for students of public health and public health bacteriology. It is a sound guide to established practice and though not stimulating, is clear, concise and easily read. It will probably be found less useful by those who seek guidance on the application of epidemiological methods to new problems. The authors acknowledge in their preface that these methods are now being used more widely but the fact that they have chosen to take their examples from, and centre discussion round, infectious diseases will not help the student to understand the way in which lessons learned from the study of measles can be applied, for example, to mental disease.

**Collected Papers of the Mayo Clinic and the Mayo Foundation.** Vol. 48. 1956. (Pp. viii + 788; illustrated. 87s. 6d.) Philadelphia and London: W. B. Saunders Co. 1957.

The policy behind the production of these annual volumes of papers from the Mayo Clinic is such that the reader does not necessarily expect a complete tracing of the tenuous and irregular growing edge of surgery, but rather evidence that surgical procedures have become established. He will thus not be surprised that there is no mention of the position of hormonal surgery in cancer, and he will probably rightly conclude from its omission that the subject has not yet developed to the stage at which it can be sold as a guaranteed article to the shrewd and critical American public. The volumes must be judged therefore by what they do contain and not by what they do not pretend to contain, and the reviewer has an embarrassment of riches in his choice of what to note.

In the cardiac surgery section, two of the most striking articles are on surgical correction of ventricular septal defects which has been done in 36 cases, and on resection and grafting for aneurysm and thrombotic occlusion of the abdominal aorta. The latter operation has been performed in 59 cases with 7 deaths for aneurysm, and in 47 cases with 2 deaths for thrombotic occlusion. In the alimentary tract section, there are six articles on benign tumours of the liver, but formal hemi-hepatectomy with preliminary vascular control does not seem to have been attempted. Four articles on resection of the colon for diverticulitis reflect the increasing frequency of this procedure.

In the section on the ductless glands, it is interesting to note that carcinoma was the cause of 46 out of 130 nodular lesions of the thyroid gland in children, and that injury of the recurrent laryngeal nerve during thyroidectomy seems equally common (or, more strictly, uncommon) in the practice of both the surgeons that do and those that do not expose the recurrent laryngeal nerves as a routine.

In the head, trunk, and extremities section one notes that hemipelvectomy is now regarded as a routine standard procedure, 50 cases of malignant tumour having been treated in this way. The development of parotidectomy for parotid tumours has been surprisingly slow at the Mayo Clinic, especially bearing in mind the pioneer work at the Clinic of Sistrunk, and of Adson and Ott. The article by Judd calling for a "much more thorough surgical approach than was used formerly" is therefore an interesting pointer. The article on operative cholangiography in the radiology section also shows a change of attitude. Previously, the surgeons of the Mayo Clinic have seemed rather hostile to this procedure, on the grounds that it is hardly worth the time it may necessitate, and that it is often misleading. The excellent article by Ferris and Weber is, however, very favourable to operative cholangiography. Perhaps the key to the change of attitude is provided by the sentence emphasizing that the success of the test depends on attention to detail, and on the close co-operation of the radiologist with the surgeon and anæsthetist.

President—I. SIMSON HALL, F.R.C.P.Ed., F.R.C.S.Ed.

[*November* 1, 1957]

## Otosclerosis, a Twenty-year Retrospect

### PRESIDENT'S ADDRESS

By I. SIMSON HALL, F.R.C.P.Ed., F.R.C.S.Ed.
*Edinburgh*

IN the middle nineteen-twenties the fenestration operation was not unknown in Edinburgh and my predecessor, Dr. John S. Fraser, had already done some of these operations, but abandoned the method on account of its dangers, as did Jenkins in London, and Bárány in Sweden.

My interest in the surgery of otosclerosis was aroused by the Address which Professor Maurice Sourdille, then of Nantes, gave to this Section in May 1930 (*Proceedings*, **23**, 1443). Since the common attitude to otosclerosis was entirely defeatist the work described by Professor Sourdille could not fail to arouse interest and curiosity.

At this period the dangers of the operation were of paramount consideration, and it was considered by many to be unjustifiable. This outlook dictated the method, and was the reason for the multi-stage operation practised by Professor Maurice Sourdille, and indeed continued to this day by some outstanding surgeons on the Continent.

Throughout this time Professor Holmgren's name was one to conjure with otologically, and a visit to Stockholm in 1938 provided many ideas particularly regarding the use of the operating microscope.

It was not until the introduction of chemotherapy that we could safely undertake the single-stage procedure as was demonstrated in the first instance by Julius Lempert. It is perfectly true that at the present time I do not use routine antibiotics at fenestration, but the knowledge that they are available if needed gives confidence and peace of mind. My earliest successful case which still retains the original improvement in hearing was commenced in 1936 and completed in 1937.

#### PATHOLOGY

In the course of work such as this it is inevitable that interests other than those in the merely technical aspects of the subject are aroused. Interest in the pathology of this condition one might say is traditional in Edinburgh. J. S. Fraser was one of the keenest students of diseases of the temporal bone in this country, and I am glad to claim friendship with Professor Felix Nager of Zurich, for to study in his laboratory I owe a great deal of the early stimulus to investigate the pathological background of otosclerosis.

The theories of the origin of otosclerosis fall roughly into three groups. We have the vascular theory originally suggested by Wittmaack, and more recently brought up to date by Dorothy Wolff. There is the group of theories of absorption by lacunar erosion and progress of the disease along the blue mantle; this was held fairly strongly by Professor Nager. And finally we have those theories which rest upon the embryological remnants which are found in the temporal bone.

Practically all these theories assume a disease entity. Some have suggested that there might be some underlying condition which predisposed to the onset of the disease. I started myself from this standard position that there was a disease and that it was necessary to discover the cause, to study its course and to follow it through the various stages.

After examining a very large number of sections I was struck by the fact that there was no evidence of spreading disease. In fact I could discover nothing but the signs of healing of bone. This seemed to me the more remarkable because the material I was examining was not post-mortem material from patients chiefly in the later age groups, but was bone taken from young people with, in many cases, a short history of deafness and a progressing disability.

If one was able therefore to discover nothing but signs of bone reconstruction, the conclusion seemed to be inescapable that there had been an acute condition present at some time

during the past. This was borne out to some extent by the presence in one or two cases of osteoclasts—but these were for the most part degenerated. As the condition which brought the patient to operation was increasing deafness, healing and increase of deafness seemed inseparable, and re-orientation of ideas seemed necessary here, and because one had been conditioned to accept otosclerosis as a disease entity, it was some time before I could bring my mind to accept the possibility that in fact we were dealing with a healing process in bone and not with a disease at all. Instead of trying to explain the changes of otosclerosis by new or unusual types of bone process, it seemed to me that if otosclerosis could be explained within the commonly accepted ideas of bone pathology we were more likely to approach the core of the problem.

Two questions therefore appeared to require an answer in this conception of the pathology of otosclerosis. First of all what was the condition of the bone originally, which predisposed it to this particular change. Secondly, what was the condition which triggered the healing process?

To begin with there is a sudden, probably inflammatory, condition of the bone in which osteoclasis plays a large part. There is sharp reaction in the bone which is evident from the production of hyperostosis. I have been able to show that hyperostosis is not the result of prolonged inflammation but is one of the earliest changes in otosclerotic bone and is probably dependent upon the activity of the first stage of the condition. Why, therefore, should the bone in a particular part of the labyrinth capsule undergo this change? I believe that in some of the other conditions affecting the temporal bone we may find some assistance in understanding this particular process. For instance, Paget's disease has been called a localized form of otosclerosis. Fragilitas ossium has many characteristics in common with otosclerosis, in that it has been stated that between 40% and 60% of all cases of fragilitas ossium suffer from otosclerosis. It is noteworthy also that in fragilitas ossium the onset of deafness occurs with the healing of the bone, suggesting again that healing of bone and deafness are concurrent.

It is also noteworthy that in these diseases healed bone is characterized by the production of a mosaic pattern; this can be demonstrated in otosclerosis, in Paget's disease, and in fragilitas ossium where otosclerosis has occurred. And if indeed in fragilitas ossium 40%–60% of all cases have demonstrable otosclerosis in the labyrinth capsule, it might be reasonable to believe that the production of the mosaic pattern which we interpret as otosclerosis is, in fact, evidence of the healing of the bone. If this should be so, then otosclerosis itself, particularly in the production of a mosaic pattern such as it produces, is again merely an instance of healing bone. And this will take us still farther back to the idea that there is a fundamental embryological abnormality of the bone similar perhaps to the lack of osteoblastic tissue which is found in fragilitas ossium, which in its healing after the influence, let us say, of inflammation or other agent, produces what we call otosclerosis. In fact the two diseases may be identical.

## Anæsthesia

In the earliest stages local anæsthesia was the anæsthetic of choice, and for the first 50 patients or so I used nothing else. I found, however, that in the main, our patients were not suited to local anæsthesia and some substitute was sought. I tried basal anæsthetics commencing with oil-ether, and Avertin, and I think I have experimented with every known sequence of inhalation anæsthesia.

At present our method is that induction is carried out with thiopentone, with or without a relaxant, and following intubation, gas-oxygen is the chief agent with the addition of trilene or other inhalant gas, as considered necessary. Blood pressure is reduced to between 60 and 80 mm.Hg. Unless it is lowered to 80 mm. we rarely find there is much advantage and 80 mm. therefore is our threshold.

The use of induced hypotension in an operation of this character is a calculated risk, and it is essential that such a risk should be justifiable. Examination of results in the various groups of cases will show that the risk is justifiable.

## Training

In the selection of patients for this operation there is no substitute for careful study of one's own patients. A certain amount can be learnt from the accounts of others, but some volume of work is essential if even reasonable results are to be achieved.

I believe that in otology there is no place for the occasional fenestrator. The young man who wishes to carry out this work and achieve a measure of success must be prepared to do much hard practice which can only be obtained in the first instance upon the cadaver. I would advise those coming to cadaver work for the first time, that it is of little use to drill a few casual holes in temporal bones. I believe that it is essential that the whole fenestration apparatus should be brought into play on every occasion; this is our method in Edinburgh.

### Classification of Patients

I have taken for analysis a thousand consecutive operations. Before considering these in detail, some definition of terms is necessary. We have to know what constitutes a successful operation. We must decide whether the social adequacy index is necessary for success, and we also have to know into what groups or classes we propose to divide our patients.

I do not consider achievement of social adequacy necessary for success. That is to say I would not reject a patient for operation because I did not feel that he would reach the social adequacy line. There is no doubt that a very high percentage of successful results can be obtained if a surgeon confines himself to patients likely to reach social adequacy, but success or failure should rest I think on far wider and more practical grounds than these. Two requirements must be fulfilled in every case. The audiogram must show a significant rise, above any possible daily variation, and the patient must be convinced that real benefit has resulted from the operation.

### Grouping of Patients

For my own study, I divide my patients into the usual three groups; class 1, the ideal case; class 2, offering not quite such a high probability of success; and class 3, where the probability of success is low. I also have a group 4, which was experimental, into which no cases have gone for a long time, but which was a necessary group in the earlier stages of the operation when we had no data as to what we could or could not do with fenestration.

I feel that if a surgeon accepts a patient for operation then that patient, irrespective of what class he or she is in, is included in any statement of results. The point of studying various classes of patients is not for the patient's benefit but for the surgeon's. Because upon his experience of what is possible within each class the surgeon bases the knowledge upon which he explains to the patient what chances that individual will have of successful operation.

I have divided the patients into groups on a time basis, showing the various types of operation which have been employed. The groups are few, because only one major change in method has been made at a time, and it took me about two years to obtain statistically valid series. Another two years had to elapse before that group could be assessed properly.

The various groups are shown in Table I.

The results in each group are shown in Tables II–V.

It is interesting to study the results on a long-term basis, and the results in all cases operated upon between 1942 and 1947 are shown in Table VI. Some later deterioration can be expected and its extent is shown here.

Table I.—Grouping of 1,005 Cases

| | | |
|---|---|---|
| Improved technique | 1943 | 78 |
| Cartilage implant | 1945 | 189 |
| Contact technique | 1947 | 298 |
| Contact technique (with B.P. control) | 1950 | 440 |

### Operative Technique

[The details of operative technique were shown in the film with which the President concluded this Address.]

In the first instance I followed Professor Sourdille's second technique closely (Sourdille, 1930). His operation resembles the operation as we know it to-day. It is a matter of personal chagrin to me in that this is the technique which I originally used and yet, following personal communication with Professor Sourdille, I abandoned it and adopted his first method wherein the incus was left in place, until it became evident that there was no advantage in making difficulties where difficulties need not exist.

My own technique is, I believe, the simplest technique which I have ever practised. I have used both post-auricular and endaural incision, but have always believed and taught that the method of soft tissue approach has nothing to do with the operation itself; the whole crux of the matter rests on making a satisfactory opening into the labyrinth in such a way that that opening will remain patent. The present method of cutting the opening in the canal is something which was developed in Edinburgh and owes nothing to anybody so far as I am aware.

The after-treatment of these operations is of considerable importance, because it may shorten or lengthen convalescence very greatly. In general my habit is to graft the cavity with a Thiersch graft, spread preferably upon linen. This method of cavity treatment has been criticized, but this method of skin grafting was based upon the results in a series of 500 mastoid operations (Hall, 1942), in which healing following skin grafting was clearly superior in my hands to healing by granulation and epithelialization. One relies upon one's own experience if it is sufficiently extensive.

My success, or rather lack of it, is very clearly seen because 13% represents the proportion of my patients who still have a discharging cavity. Unfortunately it is greater than that I had in the series of 500 mastoid cavities before we had the aid of chemotherapy. Why these clean cases should give so much trouble is one of the mysteries yet unsolved.

In my experience discharge takes two forms, one is the infected posterior cell, and the other is the leak which comes over the top edge of the attic portion of the tympanomeatal flap. The second type I find comparatively easy to cure with trichloracetic acid and a little patience, but the infected cell is more difficult because further operation may be required before it can be completely cleared up. Unfortunately the majority of these cases occur in patients in whom the cell system is large and extensive. There is no guarantee therefore that having cleared out the cells once, other and further cells will not repeat the process. This experience has induced a conservative attitude towards re-operation.

In order to shorten the period during which the patients suffer from disabilities of balance exercises are given to the patients after the method of Terence Cawthorne and F. S. Cooksey, and a class is run by the physiotherapy department.

There is no doubt in my mind that the fenestration operation produces a life-long disability in some patients and potentially in all. Patients require continuous attention at intervals which certainly increase until once every year or once in two years is sufficient, but still in the early stages supervision is essential, if the best results are to be obtained. Further, there are certain occupations or amusements which are barred for good to the patient; bathing is always a potential source of danger, and surfing and diving are absolutely forbidden. It is these disabilities which induced many workers from Professor Holmgren onwards, to experiment with other types of fenestration, including the closed fenestration, which did not involve the production of a large vulnerable cavity in the mastoid.

There is no doubt that a good result can be obtained with this particular form of operation. The chief problem here which has occupied many people's minds is to decide what type of material should be used to cover the fenestra. Professor Holmgren tried many types and the one with which he was experimenting most recently was the mucoperiosteum which normally lines and covers the ampullary part of the horizontal semicircular canal. Garson has used conjunctiva. Suggit has used skin, and I also have used a Thiersch graft. There is no doubt that if the same proportion of lasting improvement could be obtained as with the open fenestration, then this operation would receive a new lease of life and much greater popularity. I feel that there is a place for this type of operation, especially where climatic and other conditions render the care of a cavity difficult or impossible.

### Mobilization

There is not time to include the operation of stapes mobilization, but I wish to bring that operation into focus. I believe that this operation has come to stay. It has very definite usefulness and its scope and application are wider than those of the fenestration operation

could ever be. I do not now perform the fenestration operation until the effects of mobilization are known and have been tried. I consider that the one operation is complementary to the other.

### Revision Operation

The revision operation is an integral part of the fenestration procedure and anyone considering himself a complete surgeon in this respect ought to be prepared at any time to undertake it. I have carried out 59 revisions with the results shown in Table VII.

One of the most interesting groups is those with cartilage implant. In this group results were outstandingly good, and if all the failures could have been revised a very high final percentage of success could have been obtained.

The revision operation has been characterized as unjustifiable because of its dangers. With that opinion, of course, I could not possibly agree, and I would like to remind you of a saying of Professor Sourdille's that: "One should always in the making of a fenestra leave room for the revision." The reason for this is that when closure takes place it is frequently from the rear, i.e. from the canal forward over the ampulla, and the easiest place to start a revision is anterior of the ampulla working back towards the old opening. Sourdille's dictum has a great deal of meaning when one considers it from that aspect.

It was in studying revision cases that I came to the conclusion that one of the chief sources of failure was the accumulation of serum underneath the flap. It was for this reason that I proceeded to develop what I have called the "Contact" method of fenestration, whereby the space between the tympano-meatal flap and the membranous canal is minimal. The ideal I believe is that the membranous canal should lie just at the level of the bony wall on either side.

### Bilateral Operations

Altogether 8% of my patients have had operations upon both ears. It is quite obvious that when the second ear is operated upon successfully the effect upon the patient is not nearly so dramatic as in the case of the first operation. Apart from giving the patient a certain amount of balance in hearing and facility at the dinner table or board meeting, there seemed to be little real value, except as an insurance in case anything should go wrong with the first ear. I examined this problem using a speech audiometer in a free field. The speech audiograms make it clear that there is a very real gain in binaural hearing after operating upon the second ear.

There are quite clearly certain disadvantages in the operation, because I have found that troublesome vertigo is very much more likely after the second operation than after the first. For this reason I have always paid considerable attention to the patient's habits and occupation before consenting to operate upon the second ear.

### Changing Technique

I believe it is true to say that no six months have ever passed without alteration in some point of technique, and I would hope that our present results will help in further improvements in the future.

## Submarine Medicine on U.S.S. Nautilus and U.S.S. Seawolf

By Lieutenant Commander JOHN H. EBERSOLE

*Medical Corps, United States Navy*

### INTRODUCTION

IN the past few years the highly specialized field of submarine medicine and submarine physiology has been deeply involved in the revolutionary changes brought about by the advent of the nuclear submarines, "Nautilus" and "Seawolf". To-day there is more than promise that the problems of nuclear power will involve all fields of military medicine and this is not limited to military medicine alone, for the application of nuclear energy for civilian power, already in being in the United Kingdom, promises to bring these problems to civilian medical practitioners, particularly in the field of industrial medicine. While some of the problems met on "Nautilus" and "Seawolf" are limited to submarines because of their unique operational environment, many others apply equally to all reactor installations, either military or civilian, sea-going or shore-based. The experiences that submarine medicine has had in these initial years may, therefore, be justifiably utilized for a realization of the part that medicine will play in the nuclear age.

There are three important areas in which nuclear propulsion has strikingly added scope and depth to the field of submarine medicine. The first of these is a result of the new environmental situation created by reactor propulsion—an environment which bears little similarity to that of the conventional submarine. While understandable, it is erroneous to think of the medical problems of nuclear submarines as being a simple continuum of previous submarine problems to which has been added the factor of nuclear radiation. The environment of the true submersible, its effects and its control under prolonged submergence, represent a really new and unique entity, and radiation is but one of many factors.

The second significant change in submarine medical practice aboard a nuclear submarine lies in the necessity for strict supervision of radiation control measures during in-port periods. For the most part medical and toxicological problems of previous submarines have been minimal during in-port periods of maintenance. In contrast, in nuclear submarines, radiation control measures have actually greater significance during such periods than while at sea. It is during this time that reactor shield integrity may be broken in order to allow workmen access to the reactor system and to allow work on contaminated components in areas of radiation flux. Medical personnel must therefore be on the *qui vive* during any such period until the operation is completed in order to control exposure and to insure against spread of contamination. In quantitative terms, if alertness may be so quantitated, approximately four times more attention is required, based on relative exposure during maintenance as compared to that at sea.

The third, and perhaps most important, factor that has expanded the boundaries of submarine medicine is that on nuclear submarines a medical officer is directly assigned as a crew member, and is on board for all operations. Evaluation of the medical problems, therefore, no longer depends upon short term on-board observations in a guest capacity. The full impact of this intimacy is only beginning to be realized, but it can be assumed certainly that definition of the manifold problems cannot help but be improved. The rapid "break-throughs" in nuclear technology and the acceleration of new developments demand such intimacy for optimum results and maximum benefit to the submariner, whose health and efficiency are the prime interest of submarine medicine. This opportunity for daily, intimate, and long-term contact with the submarine and its problems may perhaps be ranked as the most important development in submarine medicine since its inception.

While this paper deals primarily with the radiation problem on nuclear submarines, it is necessary in introduction to re-emphasize the point that nuclear power represents more than just a radiation problem to submarine medicine. It is basically a study of the effect of a novel environment on the human organism.

### THE SUBMARINE ENVIRONMENT

It has been stated previously that the nuclear submarine environment is unique; it is necessary, however, to reiterate this point, for it profoundly affects radiation control technique and, indeed, provides a leitmotiv in the formulation of the radiation hygiene programme.

The single most important factor in the environment with which we deal on nuclear submarines is the capability for long submergence independent of the Earth's atmosphere. All previous submarines have been dependent upon air, save for relatively short periods, rarely exceeding twelve hours, at which time contact with the Earth's atmosphere was re-established. Once on the surface fresh air was circulated in the ship to dilute and displace toxic atmospheric elements accumulated in the ship during its submerged period.

Surfacing of the submarine at that time was required to run diesel engines, which, in turn,

charged the electric storage batteries which propelled the ship when submerged. Operation of such diesel engines is an aerobic process—the combustion of oxygen and a fossil fuel.

The diesel snorkel has not significantly changed this situation for the snorkel tube, carrying air to the submerged submarine for her diesels, also carried fresh air to the ventilation system and to the crew as a secondary effect. Snorkelling must, therefore, be considered as a simple variant of full surface operations in which communication with the open atmosphere is maintained although the ship is submerged.

The impact of nuclear power lies in the fact that splitting or fission of the uranium atom to furnish heat for the production of steam is an anaerobic process—indeed, for technical reasons, oxygen must be excluded from the process. Given this as the basis for a propulsion system, rather than oxygen-dependent diesels, true submersible capability is achieved.

Visualize such a true submersible as a streamlined capsule operating beneath the ocean's surface. This microcosm, this sub-miniature world, must maintain an independent atmosphere and an ecology compatible not only with life, but with efficient combat life for the the personnel contained within it. A most important limiting factor in this ecology is that such an atmospheric volume is contained and finite; therefore, little atmospheric dilution of any toxic air-borne substance can be expected. We will see later how this relates particularly to the control of air-borne radioactive contamination.

In such an environment three basic conditions must be met in order to support life:

(*a*) Continuous supply of oxygen to maintain normal atmospheric concentrations.

(*b*) Continuous removal of normal human metabolic products, i.e. carbon dioxide.

(*c*) Prevention of or provision for removal of any toxic substance released by ship's equipment.

As a corollary to these a vigorous and continuing study must be made of atmospheric conditions aboard to detect and quantitate new toxic elements. Experience has shown that many of the so-called "new" elements have existed previously in conventional submarines, but were either not recognized or were quite properly disregarded, since significant concentration values were not obtained with the limited submergence times of the pre-nuclear period.

Many traps await the unwary in trying to forecast presence or degree of importance of a given toxic substance in such a finite environment. An example is that of carbon monoxide, the production of which was previously linked chiefly to diesel exhaust fumes. With the passing of diesel propulsion one might expect this problem to be minimized. On the contrary, tolerance concentrations (100 parts per million) have been reached within thirty hours submerged on nuclear submarines. The chief source now is tobacco smoke, a source not previously emphasized, yet of extreme importance with longer periods of submergence.

Another example of an apparently harmless product giving rise to trouble in this new environment is the evolution of radioactive radon gas originating from luminescent radium-painted markers. It has been standard practice for many years in our submarines to use radium-painted markers and dials for emergency illumination. Such radium, of course, will produce its radioactive daughter-gas, radon. Gaseous radon diffuses easily from apparently well-sealed components and enters the ship's atmosphere. Here it proceeds to decay into a long series of radioactive daughter elements which become associated with dust particles suspended in the air. They are then easily collected by the filtration devices which operate constantly to monitor the air for air-borne radioactivity. Fig. 1 shows a rather dramatic increase in air-borne beta activity with time submerged as the result of only six small radium-painted switch markers being present on the submarine. Note the abrupt increase in air activity after submerging—a factor of more than ten in twenty-four hours. The curve shows the gradual levelling off as equilibrium is approached in about forty-eight hours. At equilibrium, levels are about thirty times higher than when surfaced. Apart from possible biological hazard this represents a serious nuisance because radiation monitoring equipment does not distinguish between such increases due to radon and that due to the much more serious condition of a reactor system leak. One would be justifiably quite concerned by such an increase if due to a reactor system leak. It is, therefore, necessary to initiate an immediate and complicated identification technique whenever such increases occur. The only solution is to remove all such radium sources from the ship, and, indeed, from the entire navy supply system to avoid their reappearance on board. The lower interrupted curve in Fig. 1 shows the increase in air activity over a similar period after removal of the six small markers. The remaining concentration is chiefly due to the radium-painted dials on the wrist watches of crew members.

These problems, and others like them, have been solved for the most part by removal of the offending source, by insistence on more rigid leak tightness requirements in systems containing toxic materials or by substitution with less toxic materials, and by development of removal systems such as the $CO_2$ scrubber. In the design of removal equipment medical personnel have a vital contribution to make. They must furnish the design engineer with the desired allowable concentration of the toxic substance. In the case of carbon dioxide, for example, it is not feasible to build equipment which will sustain zero concentrations; a

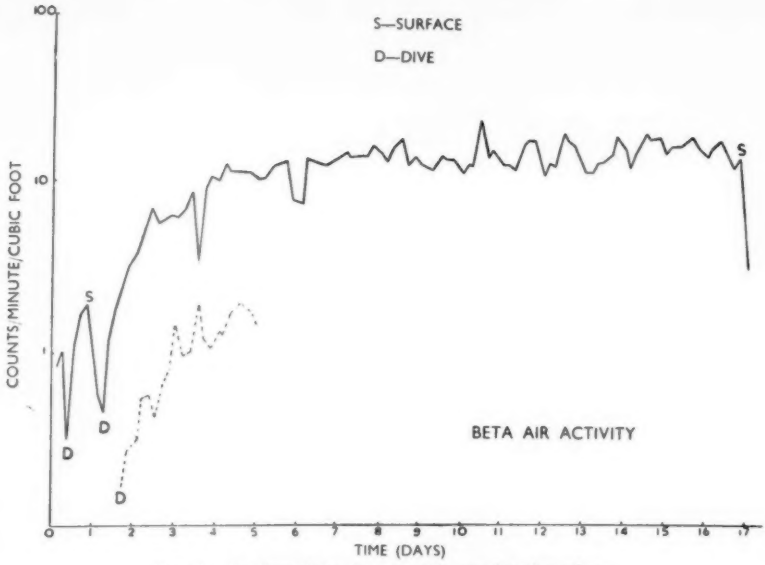

FIG. 1.—Radioactivity due to radium-painted markers.

compromise tolerance concentration must be used. Such tolerance concentrations, however, cannot be based on standard tolerances in the literature which apply usually to the eight-hour day, five days per week exposure time of industry. Aboard submerged submarines, where a 24 hours per day exposure is the case, lower tolerance limits must be applied. This principle equally is related to maximum permissible values for radiation levels as well as for toxic gases. It is, thus, one of the prime missions of submarine medicine to establish such limits by investigation and research and to communicate them to the design engineer.

The environmental factors at work here may equally apply to space medicine, and indeed, in many respects, one might simply substitute "space ship" for "submarine" in this discussion.

## RADIATION IN THE SUBMARINE ENVIRONMENT

Radiation hygiene in a submarine, an environment radically different from that of land-based reactors, presents the necessity of adapting and modifying standard control techniques. In many respects this novel environment is hostile toward efficient radiation hygiene. The following five factors, for example, will all operate to increase the shipboard radiation control problem:

(1) The closed atmosphere of a submersible allows for little dilution of air-borne radioactivity by dispersion in air.

(2) Lack of space for such requirements as decontamination stations and control areas.

(3) Proximity of living, eating, and food preparation areas to an operating reactor system with an ever-present potential contamination hazard.

(4) The submariner's work week, which is a seven-day week with no possible off-site recuperation from exposure.

(5) The constant and relatively rapid re-circulation of air through the ship's ventilation system when submerged allows for rapid spread of air-borne radioactivity from one spot to another.

If, however, one examines a submarine more closely there are many inherent factors, particularly in its architecture, that will tend to assist radiation control. First of all, the submarine is arranged horizontally like a long sealed tube. The reactor compartment section of the tube, the chief source of radiation, can affect personnel only within the compartment itself or immediately forward and aft of it. Shielding is thus simplified and the advantages of locating living areas with zero radiation levels either well forward or aft of the compartment, exploited. As far as the crew is concerned shielding in three planes only is vital, and full circumferential shielding of the system is not necessary.

An additional important factor is that our sealed tube is horizontally divided into a series of compartments by stout watertight bulkheads. This allows for rapid isolation of a given

contaminated compartment simply by shutting a watertight door and securing ventilation to that area. In the case of the reactor compartment, ventilation supply and exhaust lines pass through the compartment without openings into it. Since this is the potential area of contamination, pick-up by the ventilation system can be avoided. (Fig. 2).

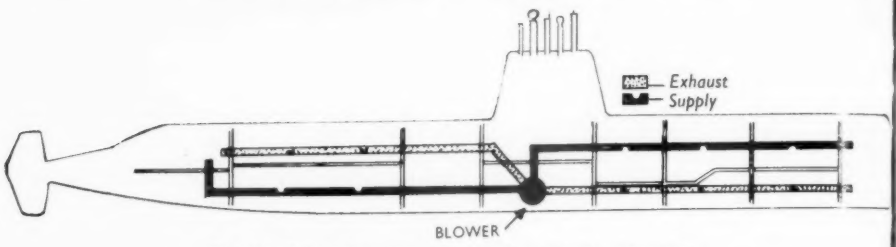

FIG. 2.—Submarine compartmentation and air recirculation.

Additional helpful factors are the small number of personnel in a submarine crew, which allows for ease of communication and control, and lack of multiple exits and entrances that must be guarded by monitoring stations in an industrial plant.

These advantages and disadvantages can be manipulated into an effective shipboard programme. For example, contamination control is built around the compartmentation system and its ease of isolation; occupancy of the reactor compartment is held to a minimum by placing master controls outside this area; contamination casualty regulations require rapid shutdown of the re-circulating ventilation cycle; protective clothing is dispersed fore and aft of the engineering spaces for accessibility.

Apart from control techniques themselves, considerable adaptation of radiation equipment is also necessary and laboratory techniques used on board must be modified to meet the peculiar environmental situation of a submarine. Radium calibration sources are prohibited due to the radon problem mentioned previously and cobalt 60 is substituted as a calibration source. Again, because of the explosion hazard and high oxygen consumption, open flames cannot be tolerated and evaporation of liquid samples must be done by infra-red lamps. Evaporation of large twenty-four-hour urine samples as a check on ingested activity is prohibited for æsthetic reasons in the confines of a submerged submarine, and must await an in-port period. At sea it would be done only on an emergency basis with an assured lowering of the popularity of medical department personnel among the crew. Volatile solvents in radio-chemical techniques must similarly be avoided. All radiation-measuring equipment must be rugged enough for use on board an operating combat ship, a requirement which, surprisingly, disqualifies many devices used in a shore-based installation.

One interesting technique modification is in the use of an end-window Geiger-Mueller tube for counting of liquid samples. In this a carefully measured 50 ml. aliquot of the liquid, usually reactor coolant water, is placed in a standard metal cup. The cup is positioned on a shelf beneath the Geiger tube. Accurate positioning of the cup in relation to the tube is important and is carefully checked with standard spacers and positioning pins. Under these fixed geometrical conditions the number of counts per minute obtained by counting the sample may simply be referred to a predetermined calibration curve of counts per minute versus microcuries per millilitre. If the calibration curve is based on an isotope whose energy approximates that of the sample very accurate results can be obtained to a level of $1 \times 10^{-5}$ microcuries per millilitre. This is a simple, rapid technique and has the advantage of quickly being taught to untrained personnel. It was soon observed that in rough seas spillage from the cup would result from this procedure. Under such conditions the cup is covered with a thin film of Saran wrap, a cellophane-type material held firmly in place by a metal lip or rim which fits over the cup. Sensitivity loss when utilizing this is 10%, a reduction to $1 \times 10^{-4}$ microcuries per millilitre as the lower limit of detection.

These are only a few of the necessary modifications to standard techniques, and, as in the case of radiation control procedures, the submarine milieu is all-important in determining the degree and type of modification necessary.

## THE REACTOR

Before discussing the personnel exposure problem aboard nuclear submarines it is necessary to describe the reactor system.

A water-cooled reactor may be considered simply as a collection of uranium atoms. Bombarded by neutrons, the uranium atoms fission, or split, and release a tremendous

amount of radiation and kinetic energy as heat, which can be removed by water flowing through the reactor lattice. The two atomic fragments remaining after the parent uranium atom is split are the fission daughters, and are intensely radioactive, emitting both gamma and beta radiation. These fission daughters cause *residual reactor radiation* long after the reactor is shut down. The reactor, then, is responsible both for prompt fission radiation (gamma and neutron) and residual radiation (gamma and beta). These are not the only sources of radiation for the reactor as it operates produces high levels of neutron radiation in its vicinity. These reactor neutrons will activate stable non-radioactive atoms present in the coolant water flowing through the reactor lattice.

As water flows through the reactor the temperature of the water is raised by the fission process and this heat, in turn, is transferred to a steam generation system through a heat exchanger or boiler. The reactor coolant water leaving the heat exchanger is then propelled back through the reactor by a pump. This closed cycle operation of coolant water is illustrated in Fig. 3. There are two important points to note about this system—first, the

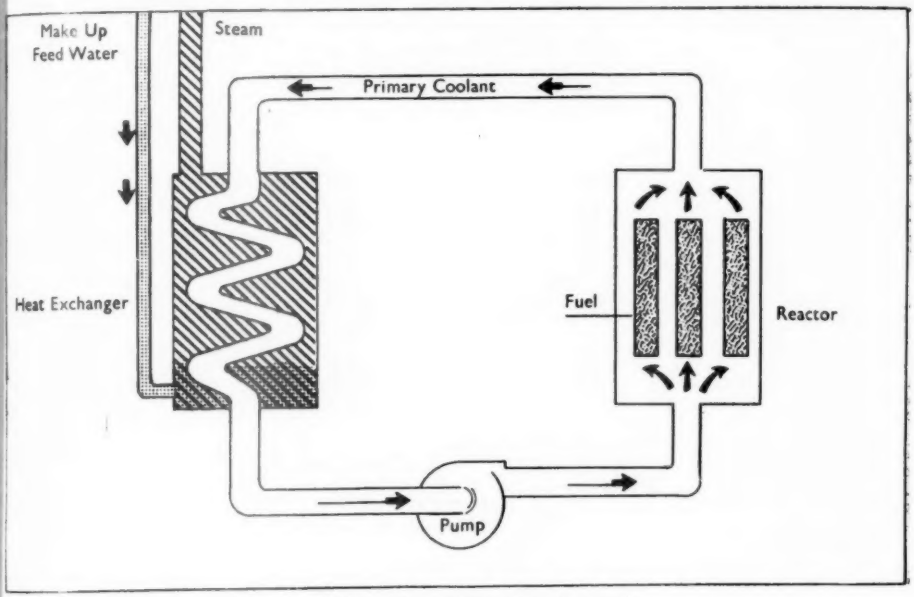

FIG. 3.—Basic reactor system and coolant cycle.

piping carrying this coolant water is leakproof; secondly, the steam generated in the heat exchanger is not radioactive. Note that the radioactive coolant water "sees" the steam only through the walls of the heat exchanger; there is no direct contact between radioactive water and the steam. This steam can thus be easily transferred from the reactor area without shielding and can be used to turn a conventional steam turbine.

Circulating in the coolant water are the neutron-activated radioactive atoms we have mentioned previously. The metallic radioactive atoms will tend to stick on the inner surface of the piping, an important phenomenon, having an effect both in raising radiation levels in the area, and in necessitating precautionary measures for contamination control whenever the system piping is opened. These radioactive atoms in the system piping continue to radiate after the reactor is shut down, and they are chiefly responsible for the gamma radiation levels in the compartment at that time. The residual fission radiation from the fission daughters in the reactor itself, being well shielded, makes little contribution. In the case of the longer-lived radioactive atoms in the coolant water, there will tend to be increasing build-up with time so that static conditions will not be met in regard to radiation dose in this area, but will tend to increase.

The compartment containing the reactor system is a section of the submarine termed the reactor compartment. This compartment, essentially a right cylinder, is divided horizontally by a deck forming an upper and lower reactor compartment. The deck is actually a thick shield, below which is placed the reactor and all the coolant system (Fig. 4).

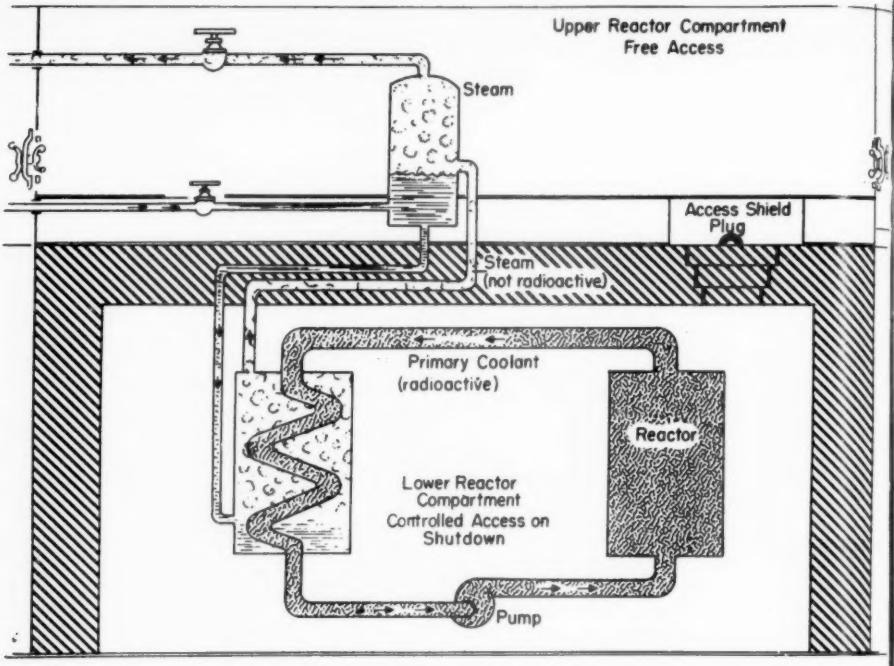

FIG. 4.—Reactor and its shielding.

Note from Fig. 4. that the upper reactor compartment sees no contaminated coolant water, only non-radioactive steam. Some gamma and neutron radiation will enter the upper level through the shield when the reactor is operating, but not in any degree which prohibits working in or manning the upper compartment. The highest level of radiation in the upper compartment is above the reactor area and sharply falls off with distance from that point. Levels in the after section of the upper compartment at full power, for example, are of the order of only 5 mrem per hour.

It must be emphasized that the reactor compartment is the only area on the ship where a radiation flux exists. All other compartments are similar to those on conventional submarines. Outside of the reactor compartment, crewmen, when submerged, receive less radiation than when ashore, due to the shielding effect of the water on cosmic radiation. This effect is noted on background radiation which decreases to a third of surface values with increases in depth of the submarine.

To return to the lower reactor compartment—the majority of the radioactivity in the coolant water has a short half life, and, because of its rapid decay, the lower area can be entered after reactor shut-down. While some reactor residual radiation remains, the chief source of radiation is gamma from the "plate-out" activated atoms inside the piping. Normally, there will be no exterior contamination present unless the system has been opened previously and contaminated coolant water spilled. Prior to entry into the lower reactor compartment after reactor shutdown, ship's personnel are preceded by medical department members who survey and monitor the area, checking for surface contamination, air-borne radioactivity, and degree of potential exposure. Permissible stay times in the lower compartment are determined and requirements for protective clothing formulated from this information. Monitoring stations are also established at exit points from the compartment and personnel leaving the area carefully checked for contamination. The monitoring points are also used as change areas if protective clothing is required.

## RADIATION EXPOSURE LIMITS—THEIR MEANING

One of the often misunderstood aspects of radiation exposure is a faulty concept of maximum permissible exposure levels, particularly in relation to presence or absence of clinical findings. In dealing with any potentially toxic material industrially, be it lead,

organic solvents, or radiation, it is necessary for operational purposes to compromise between zero exposure and the levels known to cause detectable biological effects. This compromise value, often called tolerance, is usually placed well below the threshold of minimum clinical change by a large factor—providing a threshold clinical response is typical of the toxic element in question.

In arriving at such a maximum permissible value, one uses historical observations, human clinical data, animal experimentation and laboratory data. For continuous industrial application the permissible exposure arrived at must be well below the threshold known to produce detectable change even if the exposure should last over the entire work life of the individual. This is usually accepted as being thirty years in duration.

Since for many clinical effects the rate of exposure is equally as important as the total integrated amount received over a given period, permissible levels may be expressed in terms of a rate. In the case of radiation the rate of total body exposure rather than the total dose is the more important, except for genetic, and possibly longevity effects, For example, 40 roentgen of total body gamma radiation received over a period of eight years will produce no effect on hæmatology of the individual, yet the same dose, if delivered in minutes, will produce demonstrable findings. In this latter case the time-dose relationship is such that the rate of tissue regeneration is exceeded by the rate of tissue damage.

The permissible exposure basically used in shipboard shielding design is 300 mrem per week measured in air. Note that this is not a wartime, or single emergency, or casualty exposure, but an industrial type application for continuous operation over a work lifetime. If 25 to 40 rem total body radiation is required as the threshold dose to initiate leukopenia—one of the most sensitive of biological indicators—it is obvious that one cannot depend upon clinical laboratory procedures to control radiation exposure at or below the 300 mrem/week tolerance level. In the hæmatological example the threshold of a sensitive biological indicator is 150 times greater than the maximum allowable weekly exposure of 300 mrem, far too high to be of any value.

The important and often misunderstood point is that *personnel exposure control and exposure measurement at or below tolerance levels is entirely dependent upon instrumentation. Clinical laboratory procedures are of no value in this regard.* This point is emphasized because of the repeated questions, not limited to laymen, concerning clinical findings in our personnel, particularly in relation to hæmatology. The lack of reality in these questions is obvious when the exposure pattern on "Nautilus" and "Seawolf" is analysed. This point is emphasized because of the potential danger inherent in the false idea that routine blood counts constitute a radiation hygiene programme. If such a programme were mistakenly used as a control measure, gross over-exposure by present tolerance standards would result.

A second point that requires emphasis is that, since permissible levels are well below the biological threshold, cumulative effects by definition cannot occur, since rate of tissue and cellular repair will always exceed rate of damage. Note this holds true only for effects that show a threshold, and does not apply to such non-threshold phenomena as genetic change where cumulative effects can occur independent of rate.

### The Exposure Record—"Nautilus" and "Seawolf"

The preceding statements become more emphatic when the personnel exposure data of "Nautilus" and "Seawolf" are analysed. At the presently accepted permissible exposure of 300 mrem per week, during the fifty-week period of one year a man may receive 15,000 mrem (or 15 rem). Recent recommendations from the National Committee on Radiation Protection may, in effect, officially reduce the weekly permissible exposure to 100 mrem per week. On a yearly basis this would be 5,000 mrem (or 5 rem) per man per year. Bearing the figures of 15,000 and 5,000 mrem per year in mind, note the following average exposures:

(1) "Nautilus" in 1955 .. .. 173 *mrem per man per year*
(2) "Nautilus" in 1956 .. .. 210 *mrem per man per year*
(3) "Seawolf" in 1957 .. .. 204 *mrem per man per year*

"Seawolf" exposure data is extrapolated from data obtained during the first six months of her first fully operational year.

These figures of average yearly individual exposure at their maximum represent 1·4% of the official permissible exposure and less than 5% of the proposed new permissible exposure level.

If rather than the average exposure, the maximum individual yearly exposure is used a wide differential still exists between the actual level and the maximum permissible level. The following represent the highest individual yearly exposures recorded:

(1) "Nautilus" in 1955 .. .. 1,438 *mrem per year*
(2) "Nautilus" in 1956 .. .. 2,100 *mrem per year*
(3) "Seawolf" in 1957 (extrapolated) 1,126 *mrem per year*

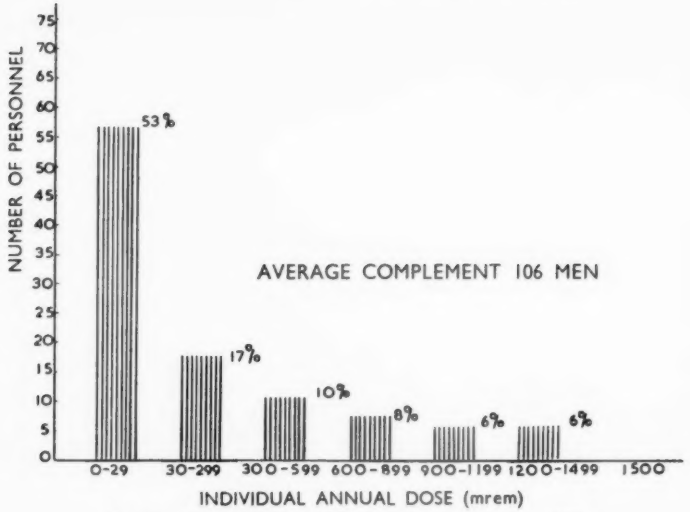

FIG. 5.—Distribution of individual exposure during 1955.

Taking the highest figure, these maximum exposures represent values of either 14% or 44% of the maximum permissible exposure per year.

Fig. 5 illustrates an important pattern of this exposure in depicting the distribution of yearly dose among the ship's population. It should be noted here that almost 50% of the crew receive no measurable exposure. The remainder of the crew spend varying periods of time in the reactor compartment and, therefore, receive some exposure. This is the only section of the ship where exposure can be received due to the conservative shielding practice described previously. The data shown in Fig. 5 is from the 1955 data of U.S.S. Nautilus but has held true since that period for both ships.

This exposure record serves to emphasize the fact that all of our experience to date is well below both the level of clinical effect and of maximum permissible exposure values.

## INSTRUMENTATION

In the absence of any dependable clinical effect to quantitate human exposure our dependence upon instrumentation is great. The data given above, for example, were obtained from personnel film badges worn by all hands on board. Such personnel exposure is measured both by the film badge and pocket dosimeter. The ship maintains its own photodosimetry programme, including capability for full processing of the film badges. Radiation monitoring equipment, counter-scalers for sample counting, radiochemical equipment, radiation sources, film processing tanks, and other equipment are located in a small, compact laboratory under medical department cognizance duplicated in both ships. Figs. 6 and 7 show views of the laboratory. In addition to the concentration of analytical equipment in the laboratory, protective clothing, including filter masks and emergency radiation measuring devices are dispersed throughout the ship.

It has been emphasized that these instruments, rather than any known biological changes, are required to quantitate personnel radiation exposure at the sub-threshold levels encountered in nuclear submarines. Such equipment may appear deceptively simple in operation but requires a thorough knowledge of its limitations, capabilities, and eccentricities for maximum usefulness.

Let us analyse some of the general problems associated with personnel dosimetry in order to point out the pitfalls in using instrumentation. Consider, for example, the film badge and pocket dosimeter. These devices are worn by all the ship's personnel when aboard and form the basis for personnel exposure records. The film badge is a metal holder, divided into a shielded portion and an open window portion. This division of the badge into two sections allows the film contained in the badge to differentiate between beta and gamma radiation by the response of the portion of the film below the shield compared to that below the open window. This also allows for some differentiation of thermal and fast neutrons if the shield is cadmium or some other element which captures thermal neutrons. In the case of beta-

FIG. 6.—Radiation laboratory.

gamma radiation the film, after developing, presents a density proportionate to the amount of radiation seen. The degree of density of the emulsion is determined by a densitometer, and the density obtained referred to a density-dose calibration curve. The calibration curve itself is based upon exposure of several films to a known standard radiation source, determination of the density for each known dose, and plotting the results as a curve. Such a curve must be made on each batch of film used.

The pencil-like pocket dosimeter is a device much like a simple gold leaf electroscope. When held up to light a fibre is visible in the eye-piece against a small scale reading 0 to 200 milliroentgen. Ionizing radiation passing through the dosimeter removes an electric charge on the fibre causing it to move across the scale in the manner of the gold leaf in a discharging electroscope. The fibre can be reset to zero by re-charging the dosimeter after any desired time or dose interval. Removal of the charge, and hence a positive reading, can occur due to insulation leakage known as "drift". Usually this is at a very low rate, but must be determined on each dosimeter. Calibration against a standard radiation source is also necessary as with film. A characteristic of dosimeters is sensitivity to mechanical trauma—an important negative characteristic aboard a ship where rough treatment may be expected.

Many variables affect results and influence interpretation in both instruments. In the case of film, storage at recommended low temperatures is important. Film storage must also provide for zero radiation exposure which must be checked by processing control film. Calibration conditions for both devices must be carefully considered, including freedom from backscatter. Both film and dosimeters are energy-dependent, and for this reason the calibration source must emit energies approximating those to be met in the field, a difficult achievement. In the case of dosimeters, the drift rate must be repeatedly checked as insulation properties may change with time and environmental conditions.

If it is assumed that all of these factors have been adequately controlled, many important variables remain to be considered. First of all, both these devices will usually be worn

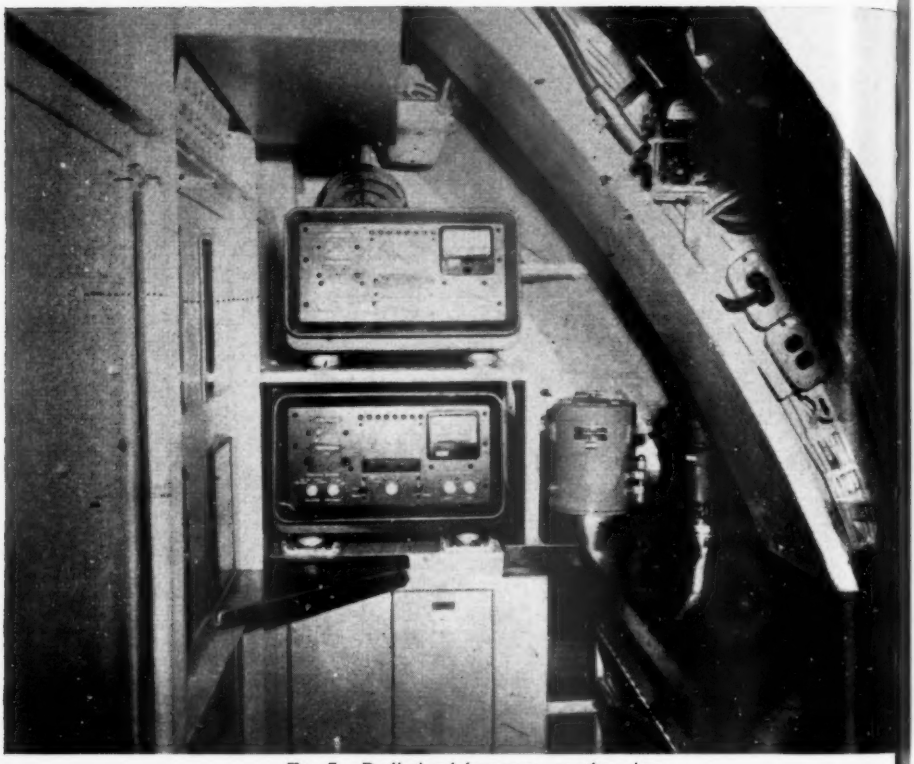

FIG. 7.—Radiation laboratory; another view.

clipped to the shirt front. In this position they do not measure a pure air dose as required by definition of the roentgen, but a complex dose disturbed by body backscatter. While one may minimize this factor by calibrating with a phantom, the angle of incident radiation in the field may differ significantly from that of the calibration situation; this is not a predictable variable within accuracy limits in the shipboard situation, but varies from position to position and with the attitude of the wearer.

If these factors are accepted, one faces an important problem in interpretation of the depth dose. The film badge is worn on the body surface and, as such, measures a surface dose which will be significantly modified by several centimetres of tissue before reaching a depth such as the median sagittal plane. The relationship between surface and depth dose can be computed, but the relationship will vary markedly with the energy of the radiation, with variation in tissue density due to presence of bone or air, and with angle of incidence of the radiation among other factors. A specific instance of large error, for these reasons, exists in those cases where the primary radiation enters posteriorly and the devices are worn anteriorly, a practical situation in lower reactor compartment work. An additional factor lies in the fact that, while total body exposure is the entity of interest, only a few square inches of body surface is covered by the film badge and dosimeter. A narrow beam may, therefore, be missed entirely, or, if detected, will be over-emphasized in relation to total body exposure.

If all of these possible variables and conditions are accepted, one is still faced with even further variables in the technique of film processing itself. These include control of purity of water used in mixing processing solutions, adequacy of darkroom conditions, and control of solution temperature during processing. Temperature control alone is a formidable problem and must be maintained rigidly throughout the processing solution with avoidance of any layering effect because temperature changes during processing will affect the emulsion as well as radiation.

Considering all of these many variables inherent in only two of the instruments used it

is not surprising that there is a search for some concrete biological change as a means of quantitating exposure to ionizing radiation. Interpretation of data obtained from such equipment requires a broad knowledge of both physical and biological factors. This is probably the strongest argument for the utilization of a medical officer in this field. Radiation is not an entity whose hazard can be simply evaluated by a glance at a meter or recording of a number, but requires careful consideration of many physical and biological factors. This is particularly important as a result of recent trends toward lower permissible exposure values, as instrument accuracy becomes more strained at the lower limits of sensitivity.

## Medical Department Duties

The medical departments of both ships consist of a submarine medical officer and two hospital corpsmen, although more corpsmen may be assigned from time to time for training purposes. The medical officer, besides his regular submarine medicine training, will have received at least an academic year of training in nuclear medicine, and will usually have had several months' experience at an operating land-based reactor prototype. The corpsmen have received at least nine months of training in radiation hygiene techniques, and also participitate in the course in nuclear engineering given to all engineering ratings.

While at sea one of the three members is on watch in the laboratory at all times. During his watch he is responsible for following a schedule of various radiation checks. For example, every four hours portable air samples are taken in the engine room and reactor compartment and processed in the laboratory, several check points in the reactor compartment are spot-monitored for gamma and neutron radiation levels as a check on shield integrity, constant monitoring equipment through the ship is checked, read, and recorded every watch, liquid samples from various portions of the engineering plant are processed and counted on a watch basis in order to maintain a constant record of radioactivity present. All radiation measuring devices must be checked daily for accuracy with standard radiation sources. Weekly, all compartments are wipe-sampled as a check on surface contamination. Every two weeks personnel film badges are collected, processed, and results recorded. When submerged, in addition to the radiation measurements, determinations of oxygen, carbon dioxide, carbon monoxide, and other gases are made every two hours.

During in-port periods if work is scheduled in the lower reactor compartment, particularly if disassembly of the system is involved, the workload increases markedly. For, in such a period, the control of contamination in the confined space of a submarine represents a great challenge. In such a period monitoring points must be manned, work times determined in radioactive areas, protective clothing requirements decided upon, and transport of contaminated material supervised. Decontamination facilities may have to be established. The situation is never static. Each task requires its own analysis and solution.

## The Future

The problems of the future with the expansion of the nuclear navy are:

(1) Need for extensive training of personnel and development of shore-based facilities for handling repair and maintenance of nuclear ships, especially in processing of contaminated equipment on the ship and on the base; establishment of dosimetry and monitoring facilities for contaminated laundry; use of material decontamination techniques.

(2) Development of more accurate instruments for relating radiation measurements to true biological dose, particularly in the field of neutron flux measurement.

(3) Development of long-term training programmes for both officer and enlisted medical personnel in the field of radiation hygiene.

(4) Continuing research on the effects of prolonged submergence, particularly in the identification and quantitation of all atmospheric elements built up under such circumstances.

But these are problems limited to the navy where nuclear power is in being rather than in potentiality—what of the significance to the civilian medical profession as a whole? A recent article in *Nucleonics* magazine, demonstrates the dramatic increase in the number of operating civilian reactors by 1960. With such acceleration medical problems are bound to appear in this area, and can potentially involve all of us, if in nothing more than in allaying the chronic semi-hysterical outlook of the public in any matter concerning nuclear radiations.

Nuclear power is the most promising development to meet the challenge of diminishing fossil fuel supplies. The events in the Middle East stress the World's dependence upon fossil fuels and the consequences of any diminished supply of them. Yet, diminish they must, and at a rapid rate by the early twenty-first century, with consequent lowering of industrial potential and standards of living if substitutes are not available. Great Britain has already launched a large-scale civilian nuclear power programme.

Specifically, the physician interested in industrial medicine will be deeply involved in evaluating and establishing future radiation control programmes, the traumatic surgeon may find wound contamination a new factor, the ophthalmologist will be used in physical

screening of personnel for posterior subcapsular opacities, the internist will be involved in diagnostic problems, not the least of which may be emotional in origin in relation to radiation; hæmatologists will also play a part.

We must not, then, consider this a limited field, confined to a handful of military specialists; but a field of potential future significance to us all. Apart from the specialized problems mentioned, the profession should be cognizant of this technology and its effects simply to answer the questions from a public beleaguered with conflicting statements related to weapons and weapon effects, so often confused with reactor radiation problems.

It would seem prudent to incorporate such subject matter into medical school curricula as soon as possible, and perhaps into present industrial medicine courses, perhaps as part of radiology, by any method which will assure our capability of dealing with the problem.

### Discussion

In reply to a large number of questions by **Squadron Leader T. C. D. Whiteside, Air Commodore D. A. Wilson, Dr. B. W. Soole, Rear-Admiral G. A. M. Wilson, Dr. D. W. H. Barnes, Mr. D. E. Barnes, Professor G. P. Crowden, Surgeon Captain C. B. Nicholson** and others, **Lieutenant-Commander Ebersole** said that body odours were overcome largely by the use of the filtration units already installed for removing $CO_2$ and CO from the atmosphere and by the submarine's ventilation system. The crew also became immune to the residual submarine odour during a long cruise, although others became aware of it when they went ashore. Dispensing with diesel propulsion had not changed this characteristic submarine smell which permeated clothing and was probably contributed to by a number of chemical factors which had not as yet been identified.

He was convinced of the need for the Naval Medical Department to be given full responsibility for the control of the environmental factors, including the radiation hazard, which were encountered during prolonged submergence in nuclear-powered submarines especially during the developmental period. This allocation of responsibility might not hold, however, for nuclear-propelled surface ships. The engineers had their hands full with their own technical problems in submergence and it would be unfair to expect them to give the necessary weight to the human factors which these obviously merited; and they might at times "rush in where angels fear to tread!" The commanding officer needed the authoritative advice of a medical officer who was technically familiar with the many complex problems involved, particularly as the total situation had not yet been evaluated.

In the United States Navy submarine medical officers and hospital corpsmen were trained in submarine physiology and plant construction as part of their initial course of instruction before they volunteered for nuclear-powered submarines and underwent further training. They had to know the component parts of the engineering plant and even to take part in routine watchkeeping duties. This additional training had paid off time and again during the development stage and early operations of U.S. Submarines Nautilus and Seawolf.

In reply to Dr. Soole Lieutenant Commander Ebersole said that saturated caustic soda was used for fission product analysis in place of ammonia hydroxide—a nasty substance to handle in a rolling submarine. Mineral acids were substituted for volatile organic acids such as glacial acetic acid. Pulse height analysis was not used for identifying specific isotopes. There were at present difficulties in the use of scintillators which might be overcome.

The neutron problem was first tackled by the contractor who was required to shield the reactor to ensure that not more than 10% of the radiation dosage was due to neutrons. The B.F.3 tube instruments for thermal neutron estimation and Radioactive Products Incorporated Model E.1 fast neutron dose rate meter were used as routine monitoring instruments. Neutron film badges (Eastman Kodak N.T.A. emulsion of 40 micron thickness) were always worn but they were only developed if the gamma dose exceeded 200 mr in a two-week period.

Neutron film development was more complex than estimating gamma dosage, as it involved the use of a microscope and oil immersion techniques.

In reply to Dr. Barnes he showed a picture of the ship's sick bay which was kept quite separate from the radiation laboratory. There was, however, very little sickness in submarines apart from the customary respiratory epidemics at the beginning of a cruise before the crew became immune to each others' strains. The number of injuries sustained on the bridge on the surface in conventional submarines was greatly reduced in nuclear-powered submarines which spent very much longer periods submerged.

In reply to Mr. Barnes he pointed out that radiation dosage was not a function of the shield entirely, as the greater exposure occurred during maintenance periods when men were beneath the shield. Little was to be gained by shaving a small amount of lead off the shield under existing circumstances, especially as at a later date the submarine might well be required to carry a large amount of lead ballast when it went to sea, a fraction of which could have been incorporated in the shield. There would be a gain from reducing the size of the reactor compartment but this would also reduce the accessibility of the component parts within it.

The effects of long-term exposure to carbon dioxide had been investigated before "Nautilus" did a prolonged dive in a submarine hull moored alongside in New London. Upwards of 20 men were exposed to 1·5% $CO_2$ in air for six weeks without any gross ill-effects being observed. But, the ideal was to provide the submariner with air that approximated to atmospheric air in composition as nearly as possible. In his opinion 1% $CO_2$ was a far better upper permissible limit to consider, particularly if smoking was to be allowed, for carbon monoxide potentiated the effects of carbon dioxide.

In conclusion, the **President** thanked Lieutenant Commander Ebersole for his most valuable address and for coming from the U.S. Submarine Seawolf to speak to the Section.

# Section of Psychiatry

President—Professor E. STENGEL, M.D., M.R.C.P.

[*October* 8, 1957]

## Reflections on the Undergraduate and Postgraduate Teaching of Psychiatry [*Abstract*]

PRESIDENT'S ADDRESS

By Professor E. STENGEL, M.D., M.R.C.P.

*London*

THE quality of general practice as well as the future of psychiatry depends a great deal on the undergraduate teaching of psychiatry which varies considerably in this country. To take the example of the two Yorkshire universities, the Department of Psychiatry at Leeds was established soon after the end of the war, while the Department at Sheffield is still *in statu nascendi*. However, the Sheffield medical students are already getting some psychiatric teaching throughout the clinical part of their curriculum. They meet the Professor of Psychiatry during their introductory clinical course, in the study of social medicine, during their periods of medical clerking and in the study of gynæcology and obstetrics. They attend the psychiatric in-patient unit once a week for three months. This attendance is to be replaced by a month's clerking shared with neurology. There is, in addition, a course of lecture demonstrations extending over two terms ending with an obligatory written and clinical examination. There is a short pre-clinical lecture course in psychology. Difficulties arise from shortage of teaching staff. In spite of these efforts psychiatry remains foreign to the student who has received hardly any basic teaching relevant to it when he starts on his clinical course which he tends to regard as an application of his pre-clinical studies. It seems essential that "the person" should be introduced from the beginning of the pre-clinical course, as was advocated by A. Meyer long ago and is now widely practised in the United States. Only when the student learns about human development and behaviour from the psychological and social aspect side by side with anatomy and physiology, will he be able to integrate psychiatry with the rest of his medical training.

Postgraduate teaching in psychiatry presents serious difficulties in the provincial medical schools. A number of universities have been running diploma courses modelled more or less on that of the London Institute of Psychiatry which is concerned with postgraduate teaching only. Some of these courses are providing systematic instruction qualifying for internal diploma examinations. They have proved a severe liability to the small university departments whose main function is undergraduate teaching. They cater for a few postgraduate students, while the majority of those in need of instruction get nothing from the universities. The number of diplomas (10 in the British Isles) is excessive. They are competing for candidates some of whom feel compelled to work for two diplomas for periods of time, an unhealthy state of affairs. The role of the postgraduate medical schools in London and their possible contribution to the needs of the rest of the country is discussed, with special consideration of psychiatry. At Sheffield no attempt is made to offer systematic courses, but only weekly seminars relevant to basic and clinical psychiatry and aiming at helping the student with his studies. It is regarded as essential to mobilize the latent teaching potentialities of the mental hospitals. In every hospital which has staff in need of postgraduate training one of the consultants is to be given the function of "Advisor in postgraduate studies" who acts as liaison officer with the university department and organizes conferences, &c., within the hospital. This scheme, which has the active backing of the Sheffield Regional Hospital Board, aims at breaking the educational isolation of the young psychiatrist not working in the university centre and at spreading the responsibility for postgraduate education fairly, instead of leaving it entirely to the university department which is unable to carry it alone, without detriment to its other commitments.

## DISCUSSION ON PHYSIOLOGICAL MEASUREMENTS OF "EMOTIONAL TENSION"

**Dr. Brian Ackner** (London):

In the everyday currency of our language we do not seem able to do without the coin "emotion", but for scientific purposes it cannot be considered to be valid currency. There is no such *thing* as emotion, it is an abstraction derived from certain subjective mental states and associated behavioural and bodily changes. However, although the concept of emotion as such cannot be the object of scientific investigation, reportable subjective mental states and observable behavioural and bodily changes seem to be reasonable fields of enquiry.

James, in his "Principles of Psychology" in 1890 said:

"Our natural way of thinking about these coarser emotions (grief, fear, rage, love) is that the mental perception of some fact excites the mental affection called the emotion and that this latter state of mind gives rise to the bodily expression. My theory, on the contrary, is that the bodily changes follow directly the perception of the exciting fact and that our feeling of the same changes as they occur is the emotion."

The James-Lange theory is no longer acceptable but its predecessor is still implicit in much of our everyday thinking. We still talk about anxiety causing bodily changes, anxiety bringing on an attack of migraine and so on. Our tacit dualism still credits the immaterial with acting on the material. For the purpose of scientific investigation emotional states should be regarded as subjective epiphenomena which may occur concomitantly with bodily changes, both being accompaniments of stressful adaptations.

If both the subjective states and the observable changes arise from a common cause it could be hoped that a full knowledge of one would provide us with some understanding of the other two. However, we cannot satisfactorily quantify the subjective state, and the behavioural expression of emotion is affected by cultural factors and influenced by the immediate environmental situation. We do not even know to what extent the various bodily changes are intercorrelated and whether changes in one field can be reliably accepted as evidence of changes in others. Nor can we quantify "emotional stress" which is dependent on factors both without and within the individual. We can expose subjects to comparable stimuli or environmental factors, but it is the significance of the latter to the individual which determines whether at any particular time they will be stressful or not.

In a study which has previously been reported, an attempt was made to overcome some of these difficulties in the following way. A group of patients was selected on the basis of subjective complaints, appearance and behaviour, all of which left no doubt that the term "severe anxiety", as generally used, appropriately described an aspect of their emotional state. In other words, this was a markedly anxious group as judged by both the common internal and external criteria. This group was compared for experimental purposes with a normal control group and another patient group, in both of which it was considered that the internal and external criteria of anxiety were absent. Instead of trying to induce and quantify stress, the opposite was attempted, namely the absence of stress by means of barbiturate-induced sleep. A number of physiological variables were recorded but particular attention was paid to changes in the amplitude of the pulse volume wave as recorded by the finger plethysmograph. Anxious subjects tend to manifest a relative peripheral vasoconstriction but the tendency is only a statistical one. It seemed possible that sleep might release a stress vasoconstrictor factor and that under suitable experimental conditions this would be manifested by the occurrence of a greater degree of vasodilatation in the anxiety group than in the other two groups. Thus, rather than vasoconstriction, perhaps the tendency to vasodilatation during sleep might be found, under suitable conditions to differentiate between markedly anxious and non-anxious subjects.

The technique and findings of this work have been described in detail elsewhere (Ackner, 1956). The results revealed that the three groups differed significantly in the size of the pulse volume during the resting state and in the increase occurring during induced sleep. The marked pulse volume increase in the anxiety group distinguished the subjects in this group from those of the other two groups.

It seemed profitable to attempt to correlate these findings with the findings of another test which also used barbiturate sedation in the study of anxiety. Shagass (1954) has described a test which he named the "sedation threshold". Starting from the observation that the more tense a patient the greater the quantity of sedation required to produce a relaxing effect he deduced that it would follow that the amount of sedative required to attain a specified end-point of sedation could be taken as a quantitative index of degree of tension. His method

was to inject intravenously Sodium Amytal at the rate of 0·5 mg. per kg. body weight every 40 sec. the subject being asked 25 seconds after each injection to repeat 5-6-7, 77, Massachusetts, &c. The sedation threshold was defined as the amount of Sodium Amytal in mg./kg. body weight required to produce an inflection point in amplitude curve of the EEG frontal 15–30 c/s activity; the inflection point must occur within 80 seconds of the clinical observation of slurred speech.

In a series of publications, Shagass has developed and expanded the application of the sedation threshold test and I shall describe briefly the way in which he has successively revised the interpretation of his findings.

The sedation threshold was first found to be correlated with "tension" as judged clinically, using neurotic and control subjects. Subsequently the term "manifest anxiety" replaced "tension" and it was considered that the greatest amount should be found in anxiety states, the least in conversion hysterics with the mixed neuroses intermediate. This expectation was found to conform to the sedation threshold results for different neurotic groups (Shagass and Naiman, 1956).

The majority of the anxiety states were found to have obsessional personalities whilst hysterical personalities, in common with patients having hysterical conversion symptoms, tended to have a low threshold. It was therefore considered that the sedation threshold was correlated not only with the degree of manifest anxiety but also with the hysteric-obsessional personality continuum. This was thought to be in line with Eysenck's introversion-extraversion dimension of personality.

The threshold was not found to be significantly correlated with degree of tension in schizophrenics but the recent acute cases were found to have lower thresholds than equally tense chronic ones. Considering that in "acute psychoses, ego functions are thought to be more impaired than in non-deteriorated psychoses of long duration, in which reparative processes have taken place" the hypothesis was formulated that the sedation threshold was negatively correlated with degree of impairment of ego functions. According to this hypothesis, the greater the degree of ego impairment, the lower the threshold (Shagass and Naiman, 1955). The sedation threshold in various psychotic categories was again found to conform to expectation, the organic cases having the lowest thresholds, followed by the acute schizophrenics, the agitated depressives and the chronic schizophrenics, with the "borderline states" having the highest threshold (Shagass, 1956).

This concept of impairment of ego function is used to explain why very agitated depressives, who are very tense, have low thresholds. Such depressions, which are also named psychotic depressions, are considered to have impaired ego functions whereas "neurotic depressions, providing they do not occur in severe hysterics, should have high ones". The sedation threshold is claimed to distinguish psychotic depressions from neurotic depressions and anxiety states, and to be able to give a good indication of the "immediate response" to E.C.T. (Shagass *et al.*, 1956).

Finally, in one of his latest papers, Shagass (1957) reports that whereas the sedation threshold was thought to be very stable on repeat testing, it is in fact found to decrease in some subjects where the degree of affective disturbance diminishes. Accepting that this must limit its value in the field of diagnosis and personality Shagass states that the sedation threshold "may now be proposed as an objective index of therapeutic change".

In view of the claims made for the value of the sedation threshold and the amount of attention it has attracted, Dr. Pampiglione and I decided to collaborate in an investigation of this test, our aim being to study the relationship of the sedation threshold to:

(1) The maximum vasodilatation occurring during barbiturate-induced sleep.
(2) The affective state of the individual at the time of the test.
(3) The diagnostic category.

Certain modifications of the procedure as described by Shagass were introduced to achieve a greater reliability and objectivity. To familiarize the subjects with the test procedure and reduce test anxiety, a preliminary EEG and plethysmographic test (without barbiturate injection) was carried out within a few days prior to the actual test. To minimize the disturbance due to the actual injection a Gordh's needle was used. This is an intravenous needle with a rubber diaphragm at the end, which after insertion into the vein can be left strapped to the arm. By this means it is possible to wait until the patient is suitably settled and then the injection is begun, without discomfort to the patient, by means of another needle inserted through the rubber diaphragm.

The course of injection was not influenced by the time at which the subject's speech might appear to slur. Instead his verbal responses were registered by means of a tape recorder synchronized with the EEG and plethysmographic record, and the injection was continued until after the patient had ceased to give any verbal responses.

The test procedure was carried out in one room with the majority of the recording apparatus housed in an adjoining room. After the EEG electrodes and finger plethysmographic

cup had been applied, the patient was allowed to relax for a period and then was interviewed by myself and by the doctor assisting with the injection procedure. As judged by his appearance, behaviour and statements about his own feelings at the time, he was rated for "manifest anxiety" on a 0–5 scale (this was not a very satisfactory procedure, but corresponded to the method employed by Shagass).

Subsequently the needle was inserted and at a suitable time Sodium Amytal was injected at a rate of 0·5 mg./kg. body weight every 40 seconds. Dr. Pampiglione was in the adjoining room supervising the recording and being able through earphones to monitor the injection proceedings and I was responsible for the timing of the injections and for making the patient repeat, 25 seconds after each injection, 57, 5-6-7, British Constitution (the latter was considered to be more suitable to our subjects than Massachusetts!). When the patient finally ceased to respond, one further injection was given and then we waited until there was no further increase in the pulse volume or until 3 minutes had elapsed after the last injection. Consciousness was then restored by means of an intravenous injection of Megimide.

Immediately afterwards we attempted to determine the time at which the patient had slurred. Starting at various points, the tape recording was played back on a number of occasions until the decision was jointly agreed by Dr. Pampiglione, the doctor giving the injection, our recordist and myself. The figure on the dial of the tape recorder was then noted and the corresponding figure on the continuous paper recording was found. From this the amount of Sodium Amytal injected at the time of slurring could also be derived.

This determination of the slur point, although made as objectively as possible, was not without some difficulty. Sometimes the speech became thicker, sometimes slower and sometimes hesitant. But we finally decided to define slurring at the first time a definite disturbance of articulation was noted. However, some patients, having slurred, afterwards articulated quite clearly until later they began to slur again. Furthermore, we noted that at times I repeated the words louder and more firmly, and yet at other times my speech actually appeared to slur!

I shall describe our plethysmographic results and Dr. Pampiglione will subsequently report our findings in respect of the sedation threshold. The test procedure was carried out on 56 psychiatric patients and in 51 of these there was a satisfactory plethysmographic record. The figure for the pulse volume increase was obtained by subtracting the maximum pulse volume occurring during the resting period prior to the test, from the maximum pulse volume occurring following the intravenous injection of Sodium Amytal. The resulting figure was then corrected for a standard 5 c.c. finger, the size of the finger tip enclosed within the plethysmographic cup having been measured following the test. In other words the results are expressed as the pulse volume increase in c.mm./5 c.c. finger tip.

It was found that the 0–5 rating scale for anxiety produced too many small groups and so this six-point scale was reduced by combining ratings 0–1, 2–3, 4–5, to give three groups which represented clinically minimal, moderate and marked anxiety. The marked anxiety group had a mean increase of 11 c.mm. and this is statistically significantly greater than the increase in the other two groups. The moderate anxiety had a larger mean increase (5·9 c.mm.) than the minimal anxiety group (4·8 c.mm.) but this difference is not statistically significant.

In the previous study (Ackner, 1956) it was found that an increase of 6 c.mm. or more distinguished a markedly anxious group from a non-anxious patient group. Using this figure in the present study it was found that 11 of the 13 (84·6%) in the severe anxiety group and 9 out of 21 (42·9%) in the moderately anxious group had an increase of 6 c.mm. or more. In the minimally anxious group 12 out of 17 (70·6%) had an increase of less than 6 c.mm.

The figures reveal a number of similarities to those in the previous study. For instance in the marked anxiety groups of both the earlier and the present study the mean initial resting pulse volumes and the mean maximum increase are within a c.mm. of each other (4·8 : 4·9; 12·3 : 11). However, there are some differences between the minimally anxious groups of the two studies. In the present study the mean initial volume is smaller (5 : 6·3), the mean maximum increase is larger (4·8 : 2·3) and 5 out of 17 patients have a pulse volume increase of 6 c.mm. or greater. These differences may be due to the different population studied but there is a possibility that the difference in the two test situations may to some extent be of importance. In the earlier study the patient, after a previous resting test, lay on a couch and gradually went to sleep, usually with the aid of an oral barbiturate. This was apparently a quite unstressful procedure, in fact many patients spontaneously reported themselves as having enjoyed their "rest period". By contrast the present procedure has an element of stress, occasioned by the presence of two doctors and the anticipation of an injection which will impair consciousness. Now it is possible to demonstrate that, even though there may be no subjective or behavioural evidence of anxiety, an anticipatory attitude can cause various bodily changes (e.g. P.G.R. (psycho-galvanic reflex), pulse-rate, respiration, vasoconstriction, &c.) all of which appear to be part of a general alerting reaction. Whilst it is

unlikely that what we call anxiety can occur without these alerting responses being present, such alerting responses need not necessarily be accompanied by the subjective or behavioural features of anxiety. The presence of bodily changes, therefore, does not necessarily record the presence of emotional disturbance.

Under suitable experimental conditions the bodily changes occurring in those whose clinical features fulfil all the subjective and behavioural criteria of severe anxiety, can validly be contrasted with those in whom such criteria are lacking. Anxiety is, however, a concept whose features can be qualified but not quantified. It is, therefore, not valid to attempt to measure anxiety by using objective measures of bodily change.

**Dr. G. Pampiglione** (London):

It is commonly believed that emotion causes visceral symptoms and influences the manifestations and course of disease.

A few hundred years ago emotion, the spring of action and conduct, used to sit in the heart, or in the belly, according to either Racine or Rabelais. Nowadays emotion is considered an agitation of the mind (as in the Oxford Dictionary) involving somehow the brain.

Clinical and intuitive methods are the most important sources of hypotheses concerning physiological mechanisms but the establishment of validity of such mechanisms cannot be based solely on clinical examples. Several studies made by physiologists on bodily changes in emotion showed that there is no rigid parallelism between the occurrence and degree of agitation of the mind that the subject shows or says that he experiences, and the occurrence and degree of measurable changes in the body.

When Dr. Ackner and I began a combined study of some physiological variables during alertness, drowsiness and sleep it was soon apparent that the questions we were trying to answer had in fact multiplied the number of problems to be faced. In our measurements of electroencephalographic, respiratory, vasomotor and dermo-electrical changes, the variability in patterns from one subject to another was very marked and often difficult to predict. There were common trends and marked individual differences but these did not appear to be clearly related to particular clinical features. Moreover, in some of our investigations the physiological changes we measured revealed no gross differences between patients and members of the staff (Ackner and Pampiglione, 1955, 1957).

The first reports of Dr. Shagass' work (1954) were therefore read with great interest. Utilizing electroencephalographic and clinical changes induced by barbiturates he described a method of obtaining a quantitative index of tension in various groups of patients. This contribution appeared of importance not only because an objective pharmacological test was introduced in the quantification of symptomatology and grouping of patients but also because Shagass suggested particular physiological substrata of emotions. Moreover, he indicated the possibility that "the sedation threshold" as he calls some implications of his test "may reflect some basic neurophysiological aspect of personality organization"; as "not only the order but also the direction of the sedation threshold differences agrees with Eysenck's data and theory on introversion-extroversion" (Shagass, 1956).

Previous work had shown that the administration of barbiturates in man may evoke fairly constant and therefore predictable changes in the activity of the brain as measured electrically, particularly in the frontal regions. In addition when barbiturates such as Sodium Amytal are slowly injected into a vein a number of clinically observable changes may follow, such as drowsiness, difficulty in articulation, appearance of nystagmus, diminution in the speed and accuracy of movements, and later sleep. In normal subjects as well as in patients I had been unable to find any close correlation between the beginning of any of these phenomena and the development of the EEG changes in response to the drug. In another investigation with Dr. B. Mandelbrote and Dr. P. Sainsbury I was unable to establish any clear relationship between the time of appearance of the fast activity in the EEG and motor relaxation as recorded by a diminution in the action potentials from the muscles of the forehead and neck.

In the early days of electroencephalography it had been suggested that the records of anxious patients contained a great deal of fast activity. This is not so if we consider patients examined when no sedative has been given for many days and when no muscle action potentials mask the EEG.

The present investigation was undertaken both to establish the validity of Shagass' test in our hands, and also to study, together with the EEG, other physiological variables such as those measured by finger plethysmography and chest pneumography, utilizing the same material and test procedure. From a pilot investigation a number of methodological problems arose. It was found that some patients were more apprehensive than others about the actual test and that the intravenous injection could not be carried out in several patients who had either inaccessible veins all the time or had marked venous constriction at the time of the test. Some patients were very restless with their arms and hands, increasing the difficulties of intravenous injection and of obtaining a reliable trace of the pulse volume waves from the finger.

Commonly when the doctor entered the room there was a change in the patient's respiratory pattern and an increase in the muscle action potentials on the EEG and a moderate vasoconstriction. When the needle was inserted further vasoconstriction was seen as well as a marked increase in muscle activity which completely masked the EEG. A few minutes later the vasoconstriction diminished and the muscle action potentials became less prominent. Each subject was therefore tested twice within a few days and on the first occasion no Sodium Amytal was injected. This precaution demonstrated the variability in the autonomic reactions between subjects to the stress of the test situation.

It should be emphasized that the sedation threshold is based, according to Shagass, upon the combined occurrence of two phenomena, namely a change in speech (slur) and a change in the EEG (alteration in the gradient of the barbiturate-induced fast activity). In order to diminish the subjective element in the evaluation of "slurring" we defined slur as a disturbance of articulation, disregarding hesitation, slowness, and changes in phonation. In addition, as already described, the intravenous injection of Sodium Amytal at the appropriate dilution for the patient's body weight continued until the patient became unresponsive even if one of us had the impression that slurring had occurred. Recently Thorpe and Barker (1957) demonstrated that 16 listeners were unable to agree regarding the onset of speech slurring in their seven patients examined with the technique described by Shagass. Our precaution of reassessing the patient's disturbance of articulation *a posteriori* by repeating several times the run of tape recorder enabled us to check how often our preliminary judgment of slurring had been erroneous. In fact the assessment of a definite slurring point was doubtful in at least a third of our cases and many subjects appeared to speak normally for a time after a single occurrence of slur.

From the EEG aspect the methodology was more complex than at first pointed out by Shagass. In fact the fast activity response to barbiturates from different regions of the brain does not have the same growth curve in all patients though usually best seen in the frontal regions. Three EEG channels from 4 scalp electrodes (mid-frontal, right upper frontal, vertex, and left Sylvian) in standard position showed a considerable variability in the amplitude growth curve in each subject on each area of the brain. In view of previous personal experience patients suspected of cerebrovascular disease or other organic cerebral lesions were excluded from our series as their EEG response to barbiturates may be even more variable.

In order not to bias our impressions I did not begin to work out the measurements of the fast activity until 50 records had been collected. The correlations between the EEG and the clinical data were made still later. The mean amplitude of the frontal barbiturate-induced fast activity (15–30 c/s) was calculated over a period of one second at regular intervals after each cubic centimetre of solution injected and a curve of the changes in the mean amplitude was built up. A special ruler had been designed by Shagass to count the waves and add up their amplitude. There is no difficulty in measuring the mean amplitude of the groups of waves with such a ruler but the measurement was very tedious and it may take up to two hours to plot the growth curve of one channel in each record. Moreover in 6 cases in which the count was repeated differences were common and often as large as 20%. This percentage of error may not appear very great to those working in the EEG field and is certainly not larger than the quantitative error of commercial wave analysers. Shagass (1954) compared his hand measurements with those of a wave analyser and found a close correlation between the two.

As a general trend the fast activity from the frontal regions is minimal at first but during the injection it tends to increase and eventually a maximum amplitude is reached. The curve obtained according to Shagass should be an S-shaped pharmacological curve, the final plateau being preceded by a fairly steep rise. The point at which the gradient changes is called by Shagass the "inflection point" and according to him the patient slurs within 80

seconds from this point. Such combination of events determines the "sedation threshold".

As previously described the intravenous injection in our study was not interrupted at the time of the "apparent" slurring, but was continued until the patient did not answer any longer. In this way the growth curve of the barbiturate-induced fast activity was not arbitrarily interrupted. It was found that although some of the curves obtained were S-shaped and slurring occurred near enough to the first inflexion, most of the other curves were complex with several inflexion points. In a few others the growth was slow but steady without definite inflexions until the patient was well asleep. Because of these various difficulties a definite sedation threshold as defined by Shagass could be determined in only a third of our cases. This determination was impossible in another third of the cases and appeared doubtful in the remaining third.

Our patients were divided into three groups according to the severity of their anxiety. There was no substantial difference in these three groups of patients in the amount of drug injected by the time the patient began to slur. Moreover the mean amount of drug necessary to render the patient verbally unresponsive was remarkably similar in each of the three groups suggesting that the epiphenomenon of anxiety does not bear recognizable relationship to the patient's resistance to a sedative of the kind employed. The amount of drug necessary to reach the maximum amplitude of induced fast activity was also similar in these three groups of patients. Where a "sedation threshold" could be determined there was no marked difference between patients with minimal anxiety and patients with severe anxiety.

In order to assess the relationship between the "sedation threshold" and the diagnostic categories studied by Shagass our patients were grouped as follows: (*a*) anxiety and neurotic depression; (*b*) obsessional states; (*c*) mixed neuroses; (*d*) endogenous depressions; (*e*) hysteria. The mean "sedation threshold" was found to be the same (6 mg./kg. body weight) both for the group of anxiety and neurotic depression and for the group of hysteria. This is in marked contrast with Shagass' findings and his theory of physio-pharmacological personality differences. The mean "sedation threshold" was slightly lower (5 mg./kg. b.w.) in the other three clinical groups. The amount of drug required to induce unresponsiveness was not substantially different for each of these diagnostic categories. There was no correlation between the sedation threshold and the time and amount of increase in the pulse volume waves in these groups, nor any constant correlation with the variations in pulse-rate.

When the injection of Sodium Amytal is continued at the same rate until the patient becomes unresponsive a single clear inflexion point in the curve of induced fast activity in the EEG is recognizable only in a limited number of cases. The slur therefore should be essential in deciding which of a number of inflexion points is to be used in determining the threshold. We cannot agree with Shagass that "slurring" roughly localizes the threshold while the EEG does it accurately.

It seems likely that a subjective judgment of "slurring" could unconsciously be influenced by a knowledge of the patient's emotional state (or diagnostic category) with the production of correlations not obtainable by more objective methods of investigation.

I wish to express my thanks to the Mental Health Research Fund for a personal grant in connexion with this investigation.

**Dr Peter Sainsbury** (Chichester):

Experimental studies which relate mental events and visceral changes due to autonomic activity are plentiful, but observations on changes in the activity of the skeletal muscles have not been numerous. This is surprising as changes in heart-rate or of the pupil, for example, have a less manifest relation to man's mental state than have the agitated movements of his hands or the tension in his facial muscles; and because the psychomotor behaviour of patients —their tense posture, their gestures and other expressive movements—are something we observe and avail ourselves of daily in the clinical examination and assessment of them. These muscular responses are the most conspicuous somatic manifestation of a patient's mental, and particularly his emotional, state.

The skeletal muscles can contract in only two ways: isometrically, that is, when tone increases without alteration in length; and isotonically, when the muscle shortens without change of tone and movement ensues. Ways must be found, therefore, to measure both tone and movements independently.

### A. *The Measurement of Tonic Activity*

The patient is asked to lie down, relax and remain still. Bipolar surface electrodes are strapped over the muscles whose activity is to be sampled. The muscle potentials from any active motor units are amplified and fed to an oscilloscope and pen recorder to monitor the tracing. In a tense muscle the recorded tracing is even, continuously sustained, of relatively low amplitude and free from irregular bursts of higher amplitude activity produced by movements. This low amplitude activity may be due to reflex postural tone in the muscle, or it may arise centrally as when the individual is alerted or aroused emotionally. Next, the potentials are passed to an electronic integrator which operates a counter.

### B. *The Measurement of Movements*

A movement appears on the record as a burst of activity of relatively higher amplitude, because in movement many motor units are rapidly recruited; and this type of activity is often superimposed on the sustained activity of lower amplitude due to reflex tone. To measure the movements, then, it is necessary to eliminate the effect of the tonic activity on the integrator. We have done this by placing a valve in the integrator circuit, the bias on the grid of which can be varied so that only those signals of a pre-selected amplitude are passed and counted. By inspecting the pen recording, a setting can be chosen at which all the low-amplitude, tonic activity is cut off: the larger spikes of movement remain to be counted.

When the integration reaches a certain value it triggers a valve which re-sets the integrator and passes a pulse to a pen which marks the paper record. The frequency of the marks varies with the integral (the area under the curve representing the potential); or, in practical terms, with the amount of movement the subject is making.

The procedure we use when recording movement is to have the patient sitting close to a table of a height such that he tends to rest his arms upon it: an arrangement which facilitates gestural movements of the arms. Small silver electrodes are placed over the maximum convexity of the forearm extensors and very light leads are passed to the back of the chair. The patient's clothes are then pulled over the electrodes and wires so that they are invisible to him and apparently they are soon forgotten. With this arrangement a record of shoulder elbow, wrist and finger movements is obtained. Should the patient rest his arm in a position involving continuous muscle strain—the chin supported in the cupped hand, for example—the tonic activity is usually still of a relatively lower amplitude and so not counted.

The apparatus is made to respond to the differing levels of muscular activity present in different patients by adjusting on the integrator the gains and settings which determine the amplitude of signals which will be counted.

Mr. J. C. Shaw, our research physicist, designed and calibrated the apparatus I now use at Graylingwell. At the gain commonly used, 670 microvolts give a 5 mm. deflection, and there is a linear relation between voltage and the recorded deflection of the pen. Similarly, on calibrating the integrator, a linear relation is found between the number of counts and the amplitude of the EMG tracing in millimetres. This relationship holds when the integrator is set to respond to *all* signals, as when tone in the muscle is to be recorded; and when it is set to respond only to those above 1, 2 or 3 mm. when movement is under investigation.

Satisfactory data on the daily stability of the integrator was also obtained.

### A. *Findings on Muscle Tension*

Jacobson (1938) was the first to record the action potentials in the muscles and to show they varied in a predictable way with mental activity and especially with feelings of tension. Next Malmo and Shagass (1949) showed in one of a number of valuable papers that anxious patients, on painful stimulation, had more activity in their neck muscles than did controls; and that in those patients with head complaints, presumed to be muscular, the neck muscle activity was significantly higher than in those whose symptoms were of a cardiovascular kind. Wolff (1948) also recorded electromyograms from the scalp and back muscles of anxious patients with symptoms referred to these areas and found that the activity in the muscle varied with the intensity of the symptoms.

Muscular relaxation has been developed as an effective therapy in tense patients by Jacobson and by Garmany (1952). These observations prompted Gibson and me to study, by a controlled experiment, the relation between the symptoms complained of by anxious

patients and the activity in their muscles (Sainsbury and Gibson, 1954). In order to limit the experimental conditions to the simplest and so avoid subjecting the patient to a stress situation which cannot be evaluated reliably, we measured the muscle activity occurring in our subjects when they were relaxing on a bed in a position which avoided reflex postural tone in the muscles being investigated. The sustained activity recorded under these conditions we called "*muscle tension*" to differentiate it from the activity due to postural tone, and we considered it to have a central origin.

The patient's complaints of anxiety and tension were scored by means of an inventory. The items were largely derived from a survey undertaken by Dr. Gibson, in which 29 senior psychiatrists at the Maudsley Hospital were questioned about the clinical observations by which they ascribed "tension" to a patient. Their answers clearly suggested that it is the general appearance of muscular over-activity, as judged from facial expression, posture, and so on, in the anxious patient which the majority of clinicians refer to when they describe their patients as "tense".

The patient's feelings and symptoms of anxiety and tension scored on the inventory were related to the counts of muscle activity. Records were obtained from the frontalis muscle of 30 anxious patients, and of 26 healthy soldiers, the controls. The muscle activity of each subject was counted for two 7-minute periods while he relaxed on a bed with eyes closed.

We found:

(1) The product-moment correlation between the counts for the two periods of relaxation was 0·9: the test-retest reliability of the counts was therefore satisfactory.

(2) The counts from the frontalis of the patients were significantly higher than from the controls ($P>0{\cdot}001$).

(3) Patients whose scores for feeling tense and anxious were above the median had significantly higher counts in both frontalis *and* forearm extensor muscles than those patients whose scores were below the median.

(4) A significant concordance was found between the measures of tension in four distinct muscle groups, which suggests that the body musculature as a whole received an increased innervation in patients who are anxious. This view was supported by another observation: that tense patients who complained of tremulousness or of starting unduly, symptoms which might be ascribed to a general increased innervation of muscles, had significantly more muscle tension in *both* their forearm and frontalis muscles than did patients without these complaints.

(5) Anxious patients with the symptoms referred to a definite area, such as tightness at the back of the neck, or a band across the forehead, showed significantly more activity in the muscles of that area than did those patients without such muscular symptoms.

I have recently collected further data for the hypothesis that muscle tension is positively related to emotional disturbance by measuring the activity in muscles of depressed and anxious patients on admission and again on discharge from Graylingwell. A significant decrease at the 5% level has been found.

To summarize these observations on muscle tension: the physiological measurement of it correlates with patients' anxiety scores and particularly with those complaints which may be reasonably ascribed to generalized muscle activity; also that the muscle tension is greatest in the muscle area to which the symptom is referred.

### B. *Findings on Movement*

An increase of spontaneous bodily movements might similarly be expected to form part of the picture of emotional disturbance. In fact, many of the spontaneous movements we make are commonly referred to as "nervous habits" and as "expressive movements", thereby acknowledging their relation to mental processes.

There are two categories of expressive movements we have measured. First, gestures, which accompany speech and so assist in communication; and secondly, those comparatively meaningless, self-directed fidgetings which Krout (1935) calls "autistic gestures". Everyday instances of autistic gestures are: unnecessary tie-adjusting, nail-biting, or the restlessness of the agitated patient.

A brief description of some of our experiments on these movements follows.

1) The validity of the scores of movement obtained: the counts on the EMG correlated 0·6 with those obtained by time-sampling the movements directly observed.

2) This experiment was designed to study the reliability of the movement scores. The gestures of 16 patients at Graylingwell were measured while they were interviewed for ten minutes on two occasions, separated by at least twenty-four hours. In these sessions the interviewer took the role of an interested listener, his only contribution being to encourage the patient to continue. The scores for movement during the two interviews correlated highly ($r=0{\cdot}87$). Another 21 patients sat *alone* for ten minutes on two different days. The product-moment correlation for their autistic gestures' scores was 0·76. These figures, in

addition to establishing the reliability, also suggest that the level of gestural activity is a characteristic attribute of the personality. I sought confirmation of this by correlating the movement scores made by these patients, while filling up a questionnaire, when alone, and while being interviewed. The concordance between the movements made in these three situations was significant at the 1% level.

(3) To test the hypothesis that emotional disturbance is accompanied by increased psychomotor activity: (i) The autistic gestures of 10 patients selected for leucotomy at the Maudsley and of 15 healthy controls, were counted by the EMG. The subjects in both groups were left sitting alone in a room for two periods of ten minutes each, on two separate occasions. The patients' mean movement score was significantly greater than the controls' ($P > 0{\cdot}025$).

The 10 *patients* were re-examined three months following their leucotomies. In the 8 patients in whom the operation effected an improvement in anxiety, tension and depression, there was a significant decrease of both gesture during interview and of autistic gesture while alone. Changes in the patients' gestures were measurable, therefore, and were related to changes in their emotional state (Sainsbury, 1954).

(ii) I have recently correlated the movements made by 21 patients sitting alone (their autistic gestures) and their ratings on an anxiety scale ($r = 0{\cdot}76$); and patients diagnosed as depressive or agitated depressive made significantly fewer movements than those in whom anxiety was the predominant feature.

(4) I aimed in another experiment to relate the amount of gesture to the content of a psychiatric interview planned to include topics of a kind likely and unlikely to disturb the patient.

The interview was recorded on tape. The patient also wore a throat microphone and this was fed to a pen which marked the electromyogram and integrator record when he was speaking. In this way we were subsequently able to synchronize the content of the interview on the tape with the movement scored by the pen recorder.

12 patients were given 16 interviews. The mean movement score for the half-minute intervals in which the topics discussed with the patient were those predicted as disturbing to him, were compared with the mean score during intervals in which his feelings were unlikely to have been disturbed. In all the interviews there was more gesture in the periods when disturbing topics were introduced: this increase was significant in 14 of them.

In three interviews every utterance of the patients was *independently* rated for the disturbance of affect manifested and the ratio of movements to words was scored for each utterance. It was found that the more affectively charged the utterance, the greater was the amount of gesture.

Finally, 4 patients were interviewed on a second occasion and it was found that those topics which had been accompanied by most gestures in the first interview were also those with most gesture in the second (Sainsbury, 1955).

Changes in the innervation of the voluntary muscles have, therefore, been found with emotion and they seem to be as much part of the physiology of emotion as are the changes in visceral innervation. In the last experiment, for example, the heart-rate was recorded concurrently with the gestures and was also found to increase with the disturbing topics. Evidence is accumulating that the hypothalamus and mid-brain mediate changes in the voluntary as well as in the autonomic pathways with emotional arousal or, indeed, with arousal of a less urgent kind such as when the individual simply attends to his surroundings.

The central discharge to muscles in these circumstances can be demonstrated as changes in spontaneous movement and in muscle tension. The former are evident clinically as restlessness, or as an increase in gesture; the latter as a stiff posture, or furrowed brow. Subjectively this increased muscular innervation is described and experienced, we found, as irritability, feeling on edge, as tightness or even pain in the muscle, or simply as feeling "tense" (a term 79% of our patients used to mean that they were unable to relax muscularly).

It would be consistent with our findings, with the reports of the majority of our patients, and with what we found to be the practice of the majority of psychiatrists, if the term "tension" were limited to the muscular manifestations of the emotion.

WOLFF, H. G. (1948) Headache. New York.

Dr. **Denis Hill** (London) said that while the recognition of stress was a relatively easy clinical task and its treatment, especially by the new tranquillizing drugs, had made some progress, its measurement had always proved a baffling problem. There were different ideas about the nature of emotional tension. Could it be described only as an over-readiness to respond to meaningful stimuli, or is it an enduring state of activity within the nervous system, or perhaps a biochemical lesion? If the first of these was correct then all evidence of tension should disappear in sleep when the meaning of stimuli ceases; on the other hand if the second alternative was correct then even in deep sleep there might be some positive evidence of abnormal functions which could be related to the state called "tension". Clinical evidence concerning the sleep of tense patients favours the second hypothesis. The problem of understanding how emotional tension could persist as an organization within the nervous system as an enduring state is a problem common to all those issues concerning the relationship between neuronal and mental activity. To solve one such problem may be to solve all. For example, if we understood how memories were retained within the nervous system through waking and sleeping life, through the violent disturbances of concussion and E.C.T. and many other circumstances which profoundly alter cerebral activity, we might well understand how an emotional state such as tension could persist.

From the physiological point of view the probable mechanisms concerned with tension are largely inaccessible; only the effects are discernible. The speakers had shown how studies at two ends of the system could help in such measurement. Recent studies by Drs. Ackner and Pampiglione had shown that it was the same nervous mechanism which caused physiological arousal of the cortex and changes in the calibre of peripheral vessels. No doubt this applied too, as Dr. Sainsbury suggested, to the changes in muscular tonicity. It seemed highly probable that the mechanism involved was the much-discussed mid-brain reticular system.

Shagass' idea of a sedation threshold seemed at first sight a fairly simple thing. From his early work he had suggested that the sedation threshold is a constant for the individual, perhaps a constitutional character. Shagass' most recent paper, however, and the new evidence of Drs. Ackner and Pampiglione made it clear that the sedation threshold is not a constant for the individual, but varies with his degree of manifest tension and anxiety and with illness, and also can be altered when the techniques by which the threshold is measured are altered. Moreover it is for some patients a measurement which cannot be made because there is no clear end-point or because the two measurable factors—fast rhythm facilitation and slurring of speech—dissociate in some patients. It would seem that the sedation threshold does not vary directly with what is called clinically emotional tension, or rather that the method may point the way to differentiating various types of tension. The results of these studies on cortical function contrast strongly with those made on peripheral structures, described by Dr. Sainsbury and by Dr. Ackner. The ingenious sampling devices developed by Dr. Sainsbury enable him to observe a part of muscular functions—and he can vary his sampling mechanisms to observe any part of these functions which he wishes. Moreover this can be done with minimal stimulation or threat to the patient. The correlations with clinical tension which emerge seem quite clear, just as do those relating to vasomotor tonus which Dr. Ackner had described. These methods seem to hold great promise for future work.

The results on the sedation threshold, inconsistent with those of Shagass, which Drs. Ackner and Pampiglione had described, are not surprising. In the case of peripheral vasomotor tonus and in the case of muscular tonicity it might be surmised that the mechanisms by which the excitability of spinal motor neurones are influenced by the mid-brain reticular system are relatively simple, involving few neuronal pathways—simple that is, in comparison with the mechanisms involved when one thought of the action of the mid-brain system in the opposite direction, on the cerebral cortex.

Shagass himself evoked the idea of another variable, "impairment of ego functions", to explain the differences in threshold between anxious neurotics and anxious psychotics. It is surprising that these results place hysterics, psychotic agitated depressions and organic dementias in the same functional category.

There was little doubt that studies such as they had heard about held great promise for the future. The benefit to clinical practice and to therapeutics in psychiatry would be enormous if reliable measurement of emotional tension could be achieved. The research worker in this field is, however, always limited by the fact that the more he wishes to observe, the more he interferes with what he observes. The patient attached to a laboratory full of apparatus is liable to resemble the traveller prepared for a journey into outer space and experiences no doubt some of the apprehension which such travellers will experience. One could only hope that the ingenuity and resourcefulness which the speakers had obviously brought to bear on their work would continue to open the way for them in the future.

**Dr. Murdo Mackenzie** (London):

The opening papers have stressed the importance of measurement in the investigation of emotional tension: and it seems prudent to emphasize the need for uniformity in the use of words to denote the several entities which are being examined.

The word "depression" has been cited, but in such different contexts as to suggest a lack of precision in the employment of the term. The diagnosis covers, *inter alia*, simple depression, reactive depression, endogenous depression and agitated depression.

The word, in ordinary language, is used in two disparate ways: one connotes lowering, as for instance, in a barometer to indicate atmospheric change; the other depicts reduction in vigour, as for example, a recession in the trade cycle. The variant of meaning is rendered clear, in each instance, by the object to which it refers.

Depressive states, as observed in the clinic or consulting room, reveal similar differentiation. One patient affirms "I am all in and can face no more strain"; another declaims "It has been the same all my life. I may appear, in a sort of way, successful; but, *au fond*, I am bogus and know it".

The first averment refers, manifestly, to a sense of loss of vitality; and the second to a lowering or denigration of the individual personality, by a psychological device. It would be of assistance, then, in the delineation of states of emotional tension if the distinctive uses of the word were preserved.

The term "personality" has been quoted in the discussion; and it, too, suffers from a general lack of consistency in application. Dr. Leopold Bellak, for instance (1956), writes of the "psychoanalytic theory of personality". Dr. Margaret Mead, on the other hand, in the same series (1956), employs "personality" to denote ". . . the total pattern of the individual's behaviour . . ." The other essays show a corresponding diversity of approach.

Personality, in everyday language, suggests the notion of a distinctive individual trait; and an interesting feature of great personalities is the way they show enduring contrast in presentation. Sir Winston Churchill, for instance, came to one of his peak points in oratory in the speech on "the beaches of Britain": in this the emphasis is on an accentuation of the significance of the "here and now". President Franklin Delano Roosevelt, on the other hand, in a similar situation, created the fireside chat on the wireless; in this the emphasis in presentation resides in a diminution of the significance of the "here and now".

If personality be defined as presentation with individual contrast, the concept might be used to further the observations on muscular contraction, in individuals under conditions of strain, described in one of the opening papers. Some patients asseverate that they, invariably, respond to stress by a manifest gesture: others affirm that they, automatically, assume the "poker face". The duality might be found to correspond with differing methods of presentation in personality contrast.

Precision in the use of terms can, at all events, only assist in promoting accuracy in the quest for "physiological measurements of 'emotional tension' ".

## DISCUSSION ON NERVE PRESSURE SYNDROMES

**Dr. I. Meanock** (Reading):

*The Problem of Paræsthesiæ in the Upper Limb*

I shall discuss only those conditions in which it is believed that pressure on a nerve is a causative factor in the production of paræsthesia. Between 8% and 10% of patients attending my out-patient clinics complain of tingling in some part of the upper limb.

In the past, *cervical rib syndrome* has been invoked as one of the commonest causes of paræsthesiæ in the upper limb. The number of alternative labels given to this syndrome, such as costo-clavicular compression, rudimentary first rib, scalenus anticus syndrome and acroparæsthesiæ, indicate several of the known factors in the production of this symptom complex.

In cervical rib syndrome a variable combination of anatomical, physiological and pathological features are involved in the production of symptoms; hence, whatever synonym is used for the condition, it is never the sole factor concerned.

The tingling in the digits, so frequently associated with recurrent coldness and cyanosis, results from the vascular component, as does the pain in the deep structures of the forearm and hand, also the intermittent obliteration of the radial pulse. Characteristically these findings are reproduced by traction on the dependent limb and the deep pain is increased and cramplike when the limb is in use for prolonged periods. The tingling is accompanied by numbness in the digits and often objective changes in cutaneous sensibility. The true nervous symptoms of rib pressure include muscular wasting and sensory loss in which the distribution is quite definite. It may involve sensory changes on the thumb and radial side of the hand, with weakness of opponens and abductor pollicis, or in other cases pain and sensory loss on the ulnar aspect of the hand with ulnar-type motor changes involving the hypothenar muscles, interossei and adductors of the thumb.

Wilson (1940) has suggested that the probable explanation for the sparing of flexor pollicis brevis is that its root supply is from C.8, whereas abductor and opponens pollicis are supplied by the C.7 root.

Cervical rib syndrome is but one of the conditions in which pain and paræsthesiæ are most distressing at night. This exaggeration of pain at night is thought by Walshe (1951) to be due to the increased pressure on the nerves at the outer border of the first rib in the supine position, when the shoulders tend to fall backwards. It is at this point on the first rib that the fibres passing to the ulnar nerve and the inner head of the median nerve are gathered. Behind the inner cord of the plexus is the nerve to serratus anterior. If we accept this outer border of the first rib as the likely pressure point, it offers an explanation for the occasional weakness of serratus anterior in the syndrome of cervical rib.

As with some other causes of paræsthesiæ in the hand, cervical rib syndrome is common in middle-aged women. Sagging of the shoulders from fatigue, debility or unaccustomed use of the hands may be operative factors. That this is likely is borne out by the fact that rest

is the most effective form of treatment in all but the most severe cases, when surgery may be necessary. Rest to the affected limb is most easily achieved by wearing a sling, care being taken to ensure that the weight of the limb is carried on the unaffected side. Whether rest is accompanied by the common practice of instructing the patient in shoulder elevating exercises or not appears to be immaterial.

*Cervical spondylosis* is perhaps a major cause of pain in the upper limb. It is regrettable that this essentially radiological entity has come to be applied to a clinical syndrome. Although cervical spondylosis is probably the commonest cause of disease of the spinal cord over the age of 50, it should be remembered that some 65% of the population over this age have the characteristic X-ray appearance (Bradshaw, 1957) and hence it should be regarded as a part of senescence and usually symptomless. The most significant radiological signs are loss of normal cervical lordosis and restriction of movement, as demonstrated with films in flexion and extension and the presence of osteophytosis. Narrowing of a disc space is naturally of importance but may not be associated with posterior osteophyte formation. Such an osteophyte may be present, however, without any apparent disc narrowing.

Protrusion of the annulus fibrosus is regarded by Brain as being the more important disc lesion in the cervical region and it is to this condition and the associated changes in the adjacent vertebral margins that the term "cervical spondylosis" is applied.

The ætiology is complex and necessarily somewhat hypothetical. External trauma is thought to play but a small part: less than 25% of a recent series gave a history of an important head injury.

The frequent association of disc degeneration at several levels of the spine suggests that it may be related to the metabolic process of ageing. Local wear and tear must play a part for it has been noted that the excessive movement in joints adjacent to a congenital lesion, such as fusion of vertebral bodies, results in disc degeneration in these excessively mobile joints.

In patients with spondylitic narrowing of the disc space there is considerable variation in the direction of the lower cervical roots; rarely do they run horizontally, but rather upwards and downwards. This course necessarily brings them into contact with the lower or upper margins of the intervertebral foramen and its adjacent osteophytes.

That the nerve is compressed against the posterior wall of the intervertebral foramen by a bony spur is sometimes evident at operation, but many cases at operation do not show either angulation or compression. It is in these cases that the work of Frykholm (1951) appears to be especially important, for he has demonstrated the fibrosis of the root sleeve following stretching, angulation or compression. The result of this fibrosis is to fix and further angulate the nerve root so that movements of the neck stretch the nerve and produce symptoms.

Paræsthesiæ are a frequent complaint in cervical spondylosis and when caused by cervical myelopathy, as opposed to root irritation, cord involvement is evident because of the predominant findings in the lower limb of pyramidal tract involvement.

The onset of radicular symptoms in cervical spondylosis is usually insidious, with burning or tingling sensations sometimes accompanied by pain radiating down the upper limb into the digits. It is particularly troublesome at night. If the onset is acute, it resembles disc protrusion but more often it is chronic and relapsing, or alternatively remaining as a persistent discomfort in neck and arm. Since a single spinal posterior root innervates not only its corresponding segmental cutaneous area or dermatome, but also muscles, joints, ligaments and even viscera remote from the corresponding dermatome, pain caused by irritation of a root may radiate widely to the front and back of the chest. The pain is felt as a deep ache in the proximal muscles with periodic attacks of pain radiating more peripherally into the fingers or up into the neck.

Motor symptoms are unusual but occasionally predominate and may be so rapid in onset as to cause confusion with anterior poliomyelitis.

Slight muscular weakness and hypotonia in muscles innervated by the affected spinal nerve are not uncommon, and the tendon reflexes mediated by these muscles may be diminished. Hyper- or hypo-æsthesia within the dermatome of the affected nerve and weakness and tenderness in corresponding muscles are frequent findings. Neck movement may be surprisingly good, lateral flexion being the most severely affected. Manual pressure on the vertex increases the discomfort and upward traction on the chin often relieves it.

The features of the older clinical accounts of brachial neuritis, in which pain and paræsthesiæ spread throughout the arm to the fingers, with muscular wasting and diffuse sensory loss, may occur in cervical spondylosis, even when on X-ray only one or two disc spaces appear to be affected.

Acroparæsthesia, being defined as unpleasant tingling affecting some or all of the digits developing at night, is so common in cervical spondylosis that its presence justifies X-ray of the cervical spine. It is, however, a common symptom of cervical rib, the so-called

"housewives' neuropathy", and is invariably present in median carpal tunnel compression.

The condition of "frozen shoulder", particularly in the older age groups, is often the result of pain referral to the shoulder from root irritation. The importance of this lies in the approach to treatment, which must be directed in the first instance to the spine rather than to the shoulder.

With the increasing popularity of the diagnosis "cervical spondylosis", and the very varied neurological syndromes found in association with it, there is a very real danger that unconnected neurological disorders will be overlooked.

In the elderly patient, for instance, tingling in the finger tips with slight unsteadiness in walking can easily be attributed to cervical spondylosis if subacute combined degeneration of the cord has not been excluded. Syringomyelia has similarly been missed in the presence of a radiological finding of cervical spondylosis. The reverse situation is still encountered where after many years with a diagnosis of disseminated sclerosis a patient at last finds hope of alleviation in treatment directed to the cervical spine.

Similarly, there is the case of cervical spondylosis masquerading as motor neurone disease, where even if a brisk jaw-jerk has been recorded, the presence of impairment of vibration sense in the lower limbs should be sufficient to rule out what is purely a motor disease.

There is wide scope for diagnostic errors in elderly patients with spondylitic changes, in the pains of cardiac ischæmia, apical lung tumours or periarthritis of the shoulder-joint.

The association of paræsthesiæ of the upper limb with emotional disturbances seems to be too frequent to be a chance one. While it is true that an emotional and tense patient may magnify minor physical discomfort in the arms and neck, another explanation seems equally feasible.

It is recognized that the increased muscle tone produced by such a factor as cold, may, in spondylitic subjects, provoke symptoms. Is it not possible then that the tense, emotional and agitated patient who shows increased muscle tone by the presence of exaggerated reflexes and tremor, may not similarly provoke symptoms? It is certainly true that some of the most stubborn cases whose symptoms have resisted many months of treatment by physical means have been improved, even to the extent of losing unequivocal physical signs, on the administration of tranquillizing agents.

The lesson to be remembered, therefore, is that the diagnosis of cervical spondylitic radiculopathy must be based on the history and physical signs and not on the demonstration of radiological changes.

Mention must be made of the concept put forward by Russell (1956) that the symptoms of neuropathy in cervical spondylosis are largely due to changes in the nerve sheaths. He believes that the problem has been oversimplified by the adoption of recent views on cervical spondylosis. The tenderness of nerve trunks, so evident by tapping or stretching the nerve, depends on an abnormal state, not of the traversing nerve fibres but of the nerve sheath. There is pathological evidence of the irritating effect of spondylitic lesions on adjacent nerve sheaths.

Russell infers that pressure on a nerve or nerve root is not in itself the cause of painful neuropathy, but rather that the pain depends upon the production of a neuritis in which the important changes are in the nerve sheath and that the treatment of the neuritis is more important than attempts to treat the cervical spondylosis directly.

There appears to be a condition somewhat intermediate between cervical rib and spondylosis in which some features of both conditions may be present. I refer to housewives' neuropathy in which pain is the salient and often the only symptom. This pain is felt mainly in the proximal part of the limb and is easily reproduced by direct pressure above the clavicle. Manœuvres which compress or stretch the nerves in the shoulder region, such as resisted abduction of the upper arm, pulling on the arm and forceful external rotation of the shoulder, reproduce the pain.

Hypoæsthesia of the fingers in a glove distribution but without any reflex or muscle changes is common.

Women with drooping shoulders appear to be very prone to this condition, particularly if they undertake unaccustomed or prolonged periods of work with the hands. This intermediate group of patients is the largest but fortunately it is very amenable to treatment. Occasionally the severe case has to be admitted to hospital in order to obtain complete rest for perhaps two weeks but most cases can be satisfactorily treated as out-patients. The arm is rested in a sling while the pain is severe or continuous. After a few days, when the acute pain has subsided, a series of shoulder exercises is started and the sling is slowly discarded over a period of three to four weeks.

The exercises should be continued for several months, or relapses will occur.

One type of paræsthesiæ in the upper limb in which treatment is dramatic is *median nerve compression* where this occurs in the carpal tunnel.

Of the two groups of patients the less common type is that in which underlying pathology can be determined, such as old fracture of wrist with or without secondary degenerative change, or in whom osteoarthritis is present, or as part of rheumatoid disease—in this connexion it is worth mentioning that on follow-up I have found that carpal tunnel compression was the presenting lesion in five cases of rheumatoid arthritis; the more frequently occurring group typically consists of middle-aged women in whom the disorder, although primarily occurring in the dominant hand, later involves both hands in more than half of the cases.

The initial symptoms are always sensory and consist of a burning and tingling in the fingers, mainly at night, frequently waking the patient. The most severe nocturnal symptoms arise some hours after strenuous use of the hands. Knitting and sewing are particularly troublesome in this respect.

An aching sensation is felt deep in the wrist and may spread up into forearm and even to arm and shoulder region. Later, blunting of sensation occurs which interferes with the handling of small objects. This hypoæsthesia in the distribution of the median nerve is found in the majority of cases.

Objective sensory loss is never proximal to the wrist and palmar sensation is not usually affected because this cutaneous branch of the median nerve leaves the main trunk above and therefore lies anterior to the carpal ligament. Wasting of the outer half of the thenar eminence is more evident if the thumbs are viewed in profile, when weakness of abductor brevis and opponens pollicis is often conspicuous. The motor change, such as the weak opposition of the thumb, adds to the clumsiness in handling, due to sensory disturbance.

Typically, the fifth finger is spared but the fact that it is sometimes involved requires at least the conception of segmental overlapping to explain it, as does the frequent presence of pain in the forearm.

Ischæmia of the tendons is a likely cause for the occurrence of stiffness of the fingers when the patient awakens.

Several simple tests often help to establish the diagnosis. The tourniquet test (Gilliatt and Wilson, 1953) of ischæmic paræsthesiæ and sensory fading, after obliteration of the radial pulse, is valuable. It seems very probable that a similar ischæmic compression of the nerve takes place during sleep, when œdema of the tissues is maximal and the patient may lie on the arm.

The normal wrist, if excessively flexed, can give rise to paræsthesiæ, but if these occur within 60 seconds of flexion, it is thought to be diagnostic.

Brain (1948) has shown that pressure within the carpal tunnel is greatest in extension. This affords some explanation of the occurrence of symptoms in women whose tasks, as opposed to those of men, require extension—for example, scrubbing or polishing. Light percussion of the median nerve at the wrist will reproduce paræsthesiæ in 80% of patients. The treatment should be directed to the cause as far as it has been determined. Rest is necessarily a vital part of the management of all cases, and wrist splintage in the neutral position is effective in the majority. The immediate response to splinting the wrist is used by some as a therapeutic test. I have found hydrocortisone injection into the region of the carpal tunnel valuable in cases of recent onset.

Section of the transverse ligament, preferably by open operation, is indicated in cases resistant to simpler treatments. If muscular weakness has been present for more than one year, the results of operation are poor. In a few cases, no obvious cause is found at operation and yet relief is obtained, though sometimes only temporarily. I now have two cases under my care where operation was apparently successful, but after periods of five and thirteen months symptoms have recurred.

I believe open operation to be more successful than the blind operation where some fibres of ligament may be left intact.

Fluid retention has been mentioned as a possible factor because of the occurrence of this syndrome in pregnancy and obese subjects. On the basis of a rather flimsy hypothesis, I have used weight reduction and Diamox in addition to rest in obese subjects, and it is my clinical impression that they improve more rapidly than their asthenic sisters.

The differentiation of the main causes of paræsthesiæ in the hands is not always immediately obvious. In cervical spondylosis, although pain and paræsthesiæ are often present in the digits, they are equally found in other parts of the limb from the shoulder down, and may include the neck and chest. Sensory loss, if present, is not localized to the distribution of the median nerve, and wasting is not confined to the outer half of the thenar eminence. In fact, wasting of the hand is rare in cervical spondylosis unless there is damage to the cord at the cervical level, when signs of involvement of the sensory and motor tracts are present. Diminished tendon-jerks, particularly the triceps, are frequent in cervical spondylosis, but never found in carpal tunnel syndrome.

If costo-clavicular compression of the brachial plexus causes sensory symptoms only,

these are not limited to distribution of the median nerve. If, on the other hand, localized pressure on the inner cord gives rise to muscular wasting, involving muscles of the thenar eminence, the accompanying sensory loss and dysæsthesia are not within the median nerve distribution, but correspond to the 8th cervical and 1st dorsal dermatomes.

The condition of tennis elbow may give rise to confusion since pain and paræsthesiæ are not infrequently found in the forearm, mainly, however, on the extensor surface of the forearm and the dorsal surface of the fingers. The diagnosis can clearly be established when the symptoms are reproduced by resisted extension of the wrist.

Ulnar nerve compression, giving rise to paræsthesiæ, sometimes occurs in lesions of the elbow-joints. It is often insidious in onset and may follow years after an injury to the joint, particularly if this has resulted in a valgus deformity of the joint. Osteophytic outgrowths in arthritis of the joint may damage the nerve, as may a Charcot elbow.

Occasionally repeated minor trauma, in occupations involving constant and forceful flexion of the elbow, may give rise to a pressure neuritis with a palpable thickening of the nerve behind the internal condyle of the humerus. The earliest symptoms are pain and paræsthesiæ in the fifth finger and ulnar border of the palm; the motor changes are rarely complete.

Appropriate operation will free the nerve from pressure and sensory symptoms rapidly improve, but recovery of voluntary power is necessarily slow. Splintage is sometimes indicated to prevent a claw hand developing. It is customary to use a splint to produce flexion of metacarpophalangeal joints and extension of interphalangeal joints.

**Dr. R. W. Gilliatt** (London):

*New Methods of Investigating Peripheral Nerve Lesions*

Our interest in these problems at the Middlesex Hospital arose from a chance observation which was made there in 1950.

In November of that year an elderly man was admitted to the neurological ward under the care of Dr. M. Kremer with symptoms which we should now recognize as being due to a carpal tunnel syndrome, but which we then labelled acroparæsthesiæ without any clear idea as to their cause. The patient complained of intolerable burning pain in one arm, accompanied by tingling in the hand and fingers, these having been present for about three months, occurring in attacks which were at first mainly nocturnal. His pain and tingling later increased during the day so that by the time the patient was admitted to hospital he was unable to work and was suffering severely from loss of sleep. The patient himself had noticed that his symptoms were greatly affected by the position of his arm; for example, pain could be precipitated by holding up a book or newspaper and it could be abolished by lowering his hand and allowing it to hang down over the edge of the bed. Examination in hospital revealed no abnormal physical signs in the nervous system to account for his symptoms, but the effects of posture which he described could be reproduced in the ward. When the left arm was raised voluntarily, or when it was held passively above his head, pain in the limb became unbearable within a few minutes and lessened when the limb was lowered. For interest, a blood pressure cuff was inflated round the upraised arm to occlude the arterial supply, and we found that when this was done severe pain persisted after the arm was lowered for as long as the cuff remained inflated. Later we found that arterial arrest by itself would produce intolerable pain regardless of the posture of the limb. With rest in bed the patient's symptoms improved and after two weeks in hospital he was discharged. No definite cause for his acroparæsthesiæ had been found and although the experimental findings were of some interest they were difficult to interpret in the absence of a firm diagnosis. They remained an isolated set of observations and for two years none of us thought more about them. Soon after leaving hospital, however, the patient's symptoms recurred and during the following year motor and sensory changes developed which established the diagnosis of median nerve compression in the carpal tunnel. Eighteen months after his first admission to hospital the flexor retinaculum was divided surgically with complete relief of symptoms.

At this time the experiments that we had done with the blood-pressure cuff in 1950 were recalled and a tentative explanation suggested. Elevation of the arm above the head and obstruction of the circulation with a pneumatic cuff are both procedures which cause ischæmia of distal structures, and in this patient they had both resulted in severe exacerbation of his

paræsthesiæ and pain. It seemed likely that the damaged median nerve at the wrist had become abnormally sensitive to changes in its blood supply and that the patient's spontaneous attacks of pain might have a similar basis. Accordingly we began to use cuffs to investigate more patients with carpal tunnel syndromes and to compare them with patients with other peripheral nerve and root lesions (Gilliatt and Wilson, 1954) and also with patients with spinal and cerebral lesions affecting the hand (Gilliatt, 1955).

The information that may be obtained by a tourniquet test can be summarized as follows. In the first place, patients with carpal tunnel syndromes may not be able to tolerate arrest of the circulation by a cuff around the arm because it produces severe pain in the hand which they recognize as similar to that of their spontaneous attacks. Normal people do not get severe pain in the arm due to a pneumatic tourniquet provided that they do not contract muscles and produce ischæmic pain, but a patient with a carpal tunnel syndrome may get something very closely resembling his spontaneous symptoms, and on several occasions we have seen patients hanging their arm over the edge of the bed during a cuff test as if they were having a spontaneous attack.

For severe pain to occur in the hand and arm as a result of circulatory arrest is the exception rather than the rule in patients with carpal tunnel syndromes, and in my own series of 100 tourniquet tests done in 1952 and 1953, pain of this sort only occurred in about one case in every six. When this pain does occur it seems to be due to the direct effect of ischæmia on the median nerve at the wrist, and it will persist until that particular segment of nerve receives further blood supply. In this respect it does not really matter whether the cuff is high in the arm or in the forearm or even just above the wrist itself.

The second abnormality which may be shown by patients with carpal tunnel syndromes during circulatory arrest is tingling in the median-supplied fingers. Between a third and a quarter of my patients showed this sign which is a clear indication of a damaged median nerve; although most normal people experience some tingling in the hand during circulatory arrest it is never felt entirely or predominantly in the median fingers, the normal result being either a diffuse tingling throughout the hand or a sensation referred mainly to the ulnar fingers. In the carpal tunnel syndrome median tingling is, I think, mainly due to the effect of ischæmia on the damaged segment of nerve at the wrist and, like the pain, it does not seem to be abolished by altering the position of the cuff in the arm, provided the blood is not allowed to flow back to the region of damaged nerve.

The third thing that may happen during a cuff test is the appearance, within a few minutes, of sensory loss of a characteristic distribution or alternatively exaggeration of sensory loss already present in the hand. It is unusual for normal people to develop any definite sensory changes in the fingers within ten minutes of the inflation of a pneumatic tourniquet around the arm, but in our patients with carpal tunnel syndromes the cuff produced changes within ten minutes in more than half. This last effect of the cuff is not quite like the two previous ones that I have described, as it may occur in any patient with a peripheral nerve lesion, regardless of whether it is a median nerve lesion at the wrist, an ulnar nerve lesion at the elbow, or a lesion in the thoracic inlet or even in the cervical root. In each case sensory loss of characteristic distribution appears or becomes more obvious during ischæmia in relation to sensation in the surrounding skin.

With regard to the practical value of these tests in diagnosis, I should say that the pneumatic tourniquet has a small but definite place in the investigation of the sort of patient under discussion. Its advantages as a test are that it is cheap and simple and that it may uncover physical signs which are not obvious on formal neurological examination. It has disadvantages in that it is time-consuming and may be unpleasant, so that patients require a lot of encouragement while it is going on. Its third disadvantage is the more fundamental one that it still requires the co-operation of the patient, as it uses a question-and-answer technique like an ordinary sensory examination. This is a very considerable disadvantage as it is particularly in the "poor witness" type of patient who gives unreliable replies to all questions that one wants an objective test, which this is not. In contrast, there are now electrical tests available which provide objective information about nerve function and which require no co-operation from the patient so that they can even be done on anæsthetized patients. From my own experience there is no doubt that I would rather have an electrical test than a cuff test in a difficult case because the electrical test by-passes this problem of the unco-operative or unreliable sensory witness, but I add the rider that when and where the electrical equipment is not available there is still a place for simple tests with a pneumatic cuff.

The first electrical method that I am going to describe was introduced by Dawson and Scott in 1949. A brief electrical stimulus is applied to the median or ulnar nerve at the wrist which causes a synchronous volley of impulses to pass up the nerve trunk. As the volley passes up the arm its action potential is picked up by surface electrodes placed over the course of the nerve just above the elbow. This action potential is amplified in the usual way,

displayed on a cathode-ray tube and photographed. In this case the afferent volley contains antidromic impulses in motor fibres as well as sensory impulses; in order to obtain a purely sensory volley, Dawson (1956) devised a method of stimulating the digital nerves themselves with ring electrodes wrapped round the fingers, the afferent volley being recorded as before by surface electrodes placed over the median or ulnar nerve trunk in the arm.

In 1956 Sears and I began to use Dawson's technique to examine patients, and in order to produce a standardized clinical test we decided to restrict ourselves to stimulation of the fingers with recording of the afferent volley at the wrist; to test the median nerve we applied our shocks to the index finger and for the ulnar nerve we stimulated the little finger. With this simplified technique, we were pleased to find we could record sensory action potentials from normal median and ulnar nerves without difficulty and in a large number of controls there was no case in which the potentials failed inexplicably to appear. We then transferred our attention to patients with peripheral nerve lesions affecting the hands, and often found that the sensory action potentials were absent or delayed and reduced in size (Gilliatt and Sears, 1958).

We now use this sensory conduction test routinely in patients with sensory disturbance affecting the upper limb. To my mind it has three main advantages: in the first place it will sometimes provide evidence of abnormality when ordinary clinical examination fails to reveal it. This obviously depends on how carefully the clinical examination is done, but we have records of some patients where the most elaborate sensory tests with compass points and nylon hairs have failed to show sensory loss, yet where electrical studies have shown abnormal sensory conduction. The second advantage of the electrical test is that it provides objective evidence of abnormal function. The patient does not have to co-operate except that he has to lie still; when he has refused to lie still we have given him intravenous Sodium Amytal and still obtained our records. The third advantage of the method is that it provides information which helps to localize the level of a lesion causing sensory loss.

For this purpose we always use our sensory tests in conjunction with measurement of motor nerve conduction velocity. Motor nerve conduction studies in these cases were first carried out in this country by Simpson (1956) and his technique is very simple. It involves stimulating a motor nerve trunk at various levels in the arm, a recording needle being placed in the appropriate muscle so that the time from the stimulus to the earliest electrical sign of a muscle response can be measured. Simpson's technique, therefore, measures the conduction time in the fastest surviving motor nerve fibre supplying a particular muscle and, by stimulating at more than one level in the arm, conduction rates can be compared in different parts of the same nerve.

Let me conclude by summarizing the characteristic electrical features of peripheral nerve lesions at different levels in the arm.

(1) Lesions of the deep branch of the ulnar nerve in the palm: a long delay in motor nerve conduction between the wrist and the affected muscles is usually present with relatively normal conduction velocity in the ulnar nerve above the wrist. The hypothenar muscles are nearly always spared and show normal motor nerve conduction throughout. The sensory action potential from the little finger is usually quite normal.

(2) Median nerve lesions at the wrist: a motor delay between the wrist and thenar muscles is the typical finding: it has been present in just over half of our cases. The sensory action potential, recorded from the median nerve above the wrist when the index finger is stimulated, has been absent or else small and delayed in about two-thirds of our cases.

(3) Ulnar nerve lesions at the elbow: motor nerve conduction velocity is relatively normal in the upper arm, but is slow in the elbow region and perhaps below it. As Simpson originally suggested, the slowing is most obvious in the region of the elbow, but there is no doubt that in a proportion of these patients conduction remains slow throughout the forearm and hand right down to the muscle. The sensory action potential from the little finger may be reduced or absent at the wrist, but in mild cases a more clear-cut result is obtained by stimulating the ulnar nerve trunk at the wrist and recording above the elbow.

(4) Cervical rib syndromes: motor nerve conduction may be somewhat slow, or it may be normal. In any case the degree of slowing will be uniform throughout the length of the nerve in the arm. Except in mild cases the sensory action potential from the little finger will be reduced or absent.

(5) Cervical cord lesions and motor neurone disease: changes in motor nerve conduction velocity have generally been small, and slowing, when it has occurred, has been distributed uniformly down the nerve. Sensory action potentials are usually preserved.

(6) Cervical spondylosis is a complex problem in that the lesion may affect the cervical root or the spinal cord, or both. We have only examined a small number of these patients,

but so far it is our impression that they behave more like spinal cord than peripheral lesions.

(7) Chronic polyneuritis and peroneal muscular atrophy: these usually show gross slowing of motor conduction velocity with a small or absent sensory action potential.

## DISCUSSION: HYDROTHERAPY. IS IT OF VALUE?

**Dr. R. Harris** (Buxton):

During the period 1909–1931 a serious attempt was made to put hydrotherapy, and other forms of physical treatment, on a rational basis. It is clear that physical medicine owes a great deal to balneology (or hydrotherapy as we call it to-day). Fifty years ago the British Balneological and Climatological Society joined the Royal Society of Medicine to become its Section of Balneology and Climatology (1909). This Section in 1931 gave place to the Section of Physical Medicine.

In preparing this paper I attempted a critical survey of experimental work done on hydrotherapy and the quality and volume of physiological experiment I found fifty or more years ago surprised me. For instance, Kellog of Philadelphia (1904) set out to answer a number of questions—what do hot and cold baths and douches do to temperature control and working capacity? His apparatus, although cumbersome compared with electronic machines, was accurate enough to give reliable answers. He used full bath calorimeters, continuous rectal temperature measurements and simple mechanical ergometers to study his problems. A subject whose "working capacity" was initially 6,480 lb. was given a hot bath (112° F.) for 12 minutes with a 16% decrease in work output. Following a cold spray douche (50° F. for 30 sec.) his working capacity was restored to its initial capacity. In another subject work output was recorded continuously until fatigue was established and output fell. A cold douche (60° F.) was given and the ergogram showed a 44% increase. In other similar experiments a hot douche (112° F. for 15 sec.) decreased work output by 33%, neutral baths had no effect, and cold baths produced a 48% increase in performance. A further experiment, which further illustrates the restorative effects of cold douching, was that of a man whose initial working capacity was 6,870 lb. He rode 35 miles on a bicycle in two and a half hours. His working capacity was then measured and showed a 13% reduction in performance, which was restored to its initial value after a half-minute hot shower and a half-minute cold douche.

These experiments of half a century ago demonstrate clearly the potency of these agents. A massive volume of similar experimental work, mainly on the Continent, has been performed on the physiological effects of various applications of water—as baths, douches and sprays—hot, cold and neutral or alternating—and results expressed in terms of ergometry, plethysmography, electrocardiography and biochemistry, and by study of the blood pressure, pulse or respiration rate, urine volume and analysis, blood sugar and leucocyte count.

What I have failed to find is accurate assessment of the *clinical* value of these proceedings. This is perhaps not surprising. Hydrotherapeutic measures have, in general, been used in conditions with obscure pathology—labelled "chronic rheumatism," "sciatica", "fibrositis"—conditions well known to have variable courses, but being in the main self-limiting. In these the enthusiasm of the physician and the impressive ritual of hydrotherapy are valuable additions to the therapeutic effects of water. In the great days of the spas, hydrotherapy was itself considered to be a complete system of medicine and given for every illness. Often no treatment other than water internally and externally was given. Unfortunately neither the diagnostic criteria of that era, nor the methods of assessing

clinical results are acceptable to us. To-day hydrotherapy is no longer used alone but in conjunction with other forms of physical treatment and with drugs and general care. The tendency is still to use it in conditions of inexact diagnosis and pathology, and of relatively unknown natural history and prognosis—just the conditions in which quackery thrives, and in which accurate assessment of progress is so notoriously difficult. In these diseases and disorders even the clinical effect of drugs—a much simpler problem than that of physical therapy—is difficult to evaluate. Gold has been given for twenty-five years to patients with rheumatoid arthritis, and its value is still not known. Only this year has the Empire Rheumatism Council set up a properly controlled trial to provide an answer.

There is particular difficulty in assessing the *additional* value of a treatment when other treatments are being given at the same time. Recently we attempted to assess the value of wax baths in the treatment of the hands of in-patients with rheumatoid arthritis (Harris and Millard, 1955). Despite a complicated and detailed comparative study of 100 subjects followed for six weeks our results showed little difference between the treated and locally untreated groups. The basic regime which all the patients were having was responsible for all the gain in the locally untreated group, and most of it in the locally treated group. This is a simple example of the enormous difficulties we face in assessing the value of physical agents.

The internal use of water, by either drinking prescribed amounts of spa water, or introducing it into the body cavities has largely been abandoned and need not be discussed. "Ritual immersion" in waters considered to have specific therapeutic properties by virtue of their mineral content or radioactivity is no longer taken seriously in this country. The two principal aspects of its current use are as an exercise medium, and as a means of applying thermal or mechanical stimulation.

As an exercise medium I would agree with Coulter and Piersol (1950) that "in every condition in which the force of gravity is too great a handicap for weakened muscles the therapeutic pool is indispensable". Any hospital handling locomotor disabilities, be they rheumatic, traumatic or neurogenic, and Units where reconstructive and orthopædic surgery is practised, need pool facilities for exercise.

I am convinced of the great value of water as an exercise medium, for providing assisted, weight-eliminated or resisted exercise for paresed muscles as in poliomyelitis, and for exercising limbs where both joint and muscle are involved, as in rheumatoid arthritis. All of us have seen limbs which were clinically paralysed move in water, and I am sure that most of us have seen joints which were clinically fixed move in warm water. Relaxation of muscle spasm in neuromuscular disorders such as cerebral palsy and disseminated sclerosis can be demonstrated to anyone's satisfaction if they put such a patient in an ordinary hot bath. I know of no work which *proves* the value of pool techniques. It is not sufficient to say that the proof is clinically obvious. At one time few denied the virtues of blood letting for almost any disease: the clinical opinion then was that it was invaluable. Will a patient with poliomyelitis gain his maximal muscle power and function more quickly by exercise in water than by "dry" resisted exercise? Will the end point be the same? The patients themselves feel that exercise in water is more beneficial to them, and they would rather miss any other form of treatment than pool therapy. Patients with rheumatoid arthritis can start walking in the pool when they are not capable of weight-bearing, or even standing alone on dry land. Clinical impression and common sense indicate that this is valuable and probably leads to earlier "real" walking—but is this actually so?

Relaxation of spastic muscle takes place in warm water. Is it maintained for any useful period after leaving the pool, or can it be more efficiently produced by simpler techniques such as dry heat, or moist packs? We have recently tried to measure the relaxation produced by warm pool therapy in patients with ankylosing spondylitis. The patient's spinal profile was plotted with a posture-meter (Harris, 1955) before and immediately after thirty minutes relaxation and exercise in the deep pool, and after a further thirty minutes hot packing. The serial profiles showed real improvement in posture at each stage, and a gain of over 1 in. in height. However, we have repeated these measurements on the same subjects before and after relaxation exercises in the gymnasium—with almost exactly similar results.

Another group of patients for whom we have been using the pool are those with peripheral vascular diseases. In the limb with inadequate venous return, where stagnation and ulceration can only be controlled by bandaging or elastic stockings the external pressure of water supplies the necessary support, and exercise can be given to the foot and ankle in the weight-bearing position without the restriction of bandages, and the ankle mobilized. I am convinced that this is valuable, but my impressions are not proof.

The use of pools has received almost universal favour, and is now hardly considered "hydrotherapy". When hydrotherapy is criticized what is usually meant is the use of

water to supply skin stimulation by sprays, douches, contrast baths and whirlpool and aerated baths. There has been sufficient experimental work to demonstrate the physiological effects of hot and cold water on the body. The short-acting cold douche produces an initial peripheral vaso-constriction which is followed by hyperæmia and a feeling of well-being. There is, however, no clinical evidence to support its use in prophylaxis or in therapy.

Contrast baths, in which limbs are alternately immersed in hot and cold water have traditionally been used in conditions in which vascular spasm is present. There is no evidence that the passive exercise of dilating and constricting skin vessels has any value, and indeed it is probable that the benefit, if any, is due to the warm phase alone and that the cold phase may be dangerous. This has been recognized by gradual alterations in the technique of administering contrast baths: to-day the cold phase has gradually been shortened and the warm stage increased.

Fricke and Gersten (1952) studied the effects of contrast baths on the vasomotor response of rheumatoid arthritics. Although after a course of treatment the cold sensitivity of the rheumatoids was reduced there was little evidence of "re-education of the skin vessels", there was no correlation between this and clinical improvement and none of their patients showed marked clinical relief.

A critical study of blood flow measurements comparing effects of hot whirlpool and non-agitated baths at the same temperature has shown no difference between the two (Cohen *et al.*, 1949). However, it is again common experience that these baths feel more comforting to the patient and can be tolerated at higher temperatures.

Is the mechanical stimulation of falling water, of air bubbles, of rapidly altering thermal stimuli of value? Counter-irritation is a great standby of physical therapy, but again carefully controlled evaluation is lacking.

Let us not forget that some forms of hydrotherapy which were of value in their day have disappeared. In the era before phenobarbitone and the tranquillizers, the mental hospitals found the neutral bath a valuable sedative. The hydrotherapy department, like the padded cell and the strait jacket, has disappeared from the mental hospitals. One of the very few controlled clinical experiments I have found is on the effect of cold baths on typhoid fever. In New York Hospitals the mortality in a series of 900 cases was reduced from 16% to 7·75% by their use (Baruch, 1920). With effective drugs available this treatment is no longer necessary.

What are we left with in hydrotherapy? There is nothing in use of which the clinical value has been demonstrated by trials which will stand up to critical assessment. We have only overall clinical impressions—that exercise and relaxation in warm water is useful in the locomotor diseases and disabilities, and that the more exotic forms of hydrotherapy combined with spa ritual are useful in psychosomatic disorders.

May I, in this Jubilee Year of the Royal Society of Medicine, refer to the proceedings of the British Balneological and Climatological Society of 50 years ago? Dr. Solly of Harrogate, in a long debate on whether or not gouty patients should be treated in "salty" spas (Solly, 1907). . . . "wished to recognize fully the value of scientific experiment and felt it was obvious that no improvement in knowledge could be obtained without it . . . but many things to which scientific research seemed hostile after all turned out to be practically useful. . . . He fell back on the experience not of medical men, but of the patients." In a further paper on "The Influence of Climate upon Gout, Rheumatism and Rheumatoid Arthritis", Buckley (1907), of Buxton, suggested that owing to the lack of information on this the large centres should jointly publish their statistics.

Controlled clinical trials are urgently required in hydrotherapy. These must be done on a multi-centre basis so that adequate numbers of cases can be studied in a reasonable time and single and relatively simple problems dealt with one at a time.

**Dr. J. H. Jacobs** (London):

In the minds of most doctors, hydrotherapy has been almost entirely associated with spa treatment, yet most spa practitioners in this country have only made moderate claims for this mode of treatment. Yeoman (1951*a*) stated: "Many attempts have been made to justify specific claims for particular waters by scientific methods, but few will stand up to critical investigations. Certainly, various natural waters taken internally have an action on the body depending on their mineral contents, but so has a solution of these minerals made up by a pharmacist." He went on: "All will agree that, used externally, they produce their effect entirely owing to their mechanical and thermal properties." This rational statement is somewhat at variance with the literature still put out by the spas themselves. I quote from a brochure from one of our most famous spas. It is headed "Sulphur Baths", and reads—"These are the baths upon which, together with the waters, the reputation of . . . has been built. There are two distinct varieties, saline sulphur and alkaline sulphur water, which are used in different types of disease. The former is used chiefly in gout, rheumatism and liver disorders, and the latter in diseases of the skin."

The insistence on the word "cure", so dear to Continental Spas and so unwise when applied to the treatment of the rheumatic diseases, may be one of the reasons why Dr. Yeoman (1951*b*) writes in another article: "The decision to send a particular patient to a spa depends on the advice of the general practitioner or consultant, but it is remarkable how frequently it is the patient who initiates the idea." Perhaps this state of affairs results from the layman being rather more susceptible to pseudo-scientific propaganda than the more sceptical professional mind.

My own experience of hydrotherapy is largely limited to the treatment of the rheumatic disorders at the Arthur Stanley Institute, London, and, more recently in an investigation into the importance of hydrotherapy in a general department.

Firstly, our own minds and the mind of the patient must be quite clear on what is to be gained from this method of treatment. The patient must realize that no magical properties exist in water, and that any improvement in his condition can only be brought about by his active co-operation, and by using such muscle power as he possesses to its best possible advantage. From the physician's point of view, an accurate diagnosis is essential, and the treatment of such vague conditions as fibrositis, neuritis and panniculitis can only bring hydrotherapy into disrepute. The beneficial results he hopes to gain will be achieved solely through the hydrodynamic and thermal qualities of water. One cannot entirely leave out the psychological value of pool therapy—to the patient who may be dispirited by his previous efforts it is something new and novel, and its ritual impressive. The fact that the patient is able to use weakened muscles which otherwise may still seem to him to be paralysed, and also that early ambulation is possible, enhances the patient's confidence, increases his morale and stimulates him to further efforts.

Exercises can be graded from water-assisted to water-resisted, depending on the methods employed. In addition, the buoyancy of the water enables a range of assisted movements to be obtained in any direction, which is especially helpful in early joint mobilization. This mechanical property of water also enables heavy patients to be handled with greater ease once they are in the pool, and makes possible limited weight-bearing ambulation in the early stages of rehabilitation. Increased weight-bearing may conversely be brought about by gradually decreasing the depth of the water in the walking lane.

Of all the possible benefits to be derived from hydrotherapy, early ambulation with limited weight-bearing and the consequent early re-establishment of co-ordinated patterns of movements seems to me to be the most important—this one facet of hydrotherapy is difficult to duplicate by any other alternative method.

Hydrotherapy should be considered as a form of exercise therapy which is particularly suited to the treatment of weakened or partly paralysed muscles, but graduation to other and more vigorous forms of exercise which can be adapted to greater and maximal resistance should take place at the earliest opportunity. However, the re-education of individual muscles rather than of patterns of movements is probably more easily carried out on dry land than in the pool, owing to the difficulty of fixing and stabilizing joints in water.

The beneficial effect of heat in relaxing muscle spasm prior to exercise therapy is well accepted. The warm pool at 94° to 98° F. enables one to carry out re-educational procedures on relaxed muscles, and to obtain a maximal range of joint movement without, as Lowman (1957) puts it, the occurrence of "the pain-spasm-pain cycle". A temporary increase in peripheral blood supply occurs during the short period of immersion, but whether this is of any lasting value is a matter for speculation.

In considering the place of pool treatment in a general department the treatment of paralytic poliomyelitis immediately springs to mind, but these cases rarely appear in a general hospital within the first few months of their onset, when hydrotherapy would be

most beneficial. In the later stages other forms of exercise therapy are probably of equal or more value.

There is, of course, no place for hydrotherapy in the management of the acute stage of rheumatoid arthritis; it is the chronic patient with polyarticular involvement, stiffness, and a limited range of joint movement who is most likely to be helped in the pool by means of walking exercises, muscle re-education and by increasing the range of movements of his stiffened joints. Fortunately, with the provision of modern drugs and the availability of intra-articular hydrocortisone, these more crippled cases of rheumatoid arthritis seem to be less prevalent in general hospitals than in former days.

In osteoarthritis, it is the patient with hip involvement who is most likely to benefit from hydrotherapy. Much of the pain in the hip is secondary to capsular fibrosis and contraction, and in the warm medium of the pool it is possible to obtain adequate relaxation, which enables the physiotherapist to put the joint through an increased range of movement, and so stretch the capsule and at the same time exercise and strengthen the prime movers of the joint. I doubt whether the results so obtained are superior to those obtained with short-wave therapy and sling exercises. In post-operative orthopædic conditions, especially those involving the hip-joint or fractures of the lower limbs, hydrotherapy has its part to play by ensuring early walking re-education, preventing and reversing muscle atrophy, and avoiding osteoporosis due to prolonged disuse.

Of the spastic neurological conditions, hemiplegics benefit from early ambulation and relaxation provided they are fit enough to undergo pool therapy, and cases of multiple sclerosis, in whom weakness is the predominant feature, may also benefit, provided their balance is reasonable and their sphincters controlled. Hydrotherapy in cases of cerebral palsy is of doubtful value. To judge the size of this problem in a general hospital, I have been looking through the records of the new patients who have been attending my department for the past few months, and only 5% fall into the categories I have mentioned. In addition there are always a number of more chronic patients who would also be suitable for hydrotherapy.

Therapy in a well-equipped pool is expensive in money, time, space and in personnel, though admittedly a certain amount can be done in smaller tanks. Pool therapy can be most exhausting for both the patient and the hydrotherapist, and this factor also must be considered.

One must inevitably face the question as to what can be achieved with hydrotherapy that cannot be achieved in a department which is not equipped with a pool, for this is the case in most units of Physical Medicine in general hospitals. I have already stressed the benefits of early ambulation with limited weight-bearing, and perhaps one should also stress the treatment of the patient suffering from chronic poly-articular rheumatoid arthritis, but apart from these two categories, I doubt if hydrotherapy is superior to other and more readily available alternative methods of treatment.

I feel it is fair to say that in a general hospital a pool is a desirable facility, though by no means an essential one. Finally I should like to add that unless all concerned with this method of treatment, including the patient, have a clear picture in mind of the aims of hydrotherapy, its abuses may well outweigh its uses.

**Dr. T. G. Reah** (Harrogate):

In June 1957 we held a meeting of the Section of Physical Medicine to discuss breathing exercises. In the discussion a clinician was firmly convinced and two other speakers were doubtful of their value. It was generally agreed that there was little or no change in the objective movements of the chest after a course of exercises, and although many patients are encouraged by them, we ultimately remained ignorant as to whether or not they were useful. In respiratory disorders it is difficult or impossible to obtain comparable series of patients for trials by different methods of treatment and in any case a double-blind trial of exercises is impossible.

In general medicine there are innumerable instances of the value of a particular treatment so that regardless of control series, double-blind trials and the statisticians we accept for instance the value of digitalis and mercurial diuretics in congestive heart failure. Also, the value of the newer preparations of insulin has been largely established by observations on

individual patients and groups of patients. So it has been and still is with many of the individual forms of treatment given in Departments of Physical Medicine and we know how many electrotherapeutic measures have been abandoned as valueless and others retained while in hydrotherapy we have discarded aerated, foam and whirlpool baths.

A consideration of physiological, anatomical and mechanical principles will often suggest whether a form of treatment will help and thereafter continued observations of the patients will frequently decide for us if such a treatment is producing a quicker and better result than either no treatment at all or than some other measures would have produced. Empiricism or the practice of medicine founded on experience particularly when tempered by a critical outlook and an acute awareness of our basic obligations to patients is still worthy of a place in medicine.

It is with such an outlook that I approach the question of the value of hydrotherapy in the treatment for disorders of the locomotor system. Many patients who come to us are sent from other hospitals both teaching and non-teaching, and with few exceptions are suffering from rheumatoid- or osteo-arthritis. There is often the comment that they have had prolonged treatment at home and they are now being sent to us for the benefit of the other forms of treatment, mainly hydrotherapy, that we are able to give. After their first visit such patients are frequently sent again to us because of the improvement in their mobility that has been achieved. I realize that in addition to the various forms of therapy there is the advantage of the rest in hospital and the change in the patient's general environment.

If we accept the use of heat as a therapeutic measure—and which of us has not in our younger days, after strenuous exercise, relaxed stiff and aching limbs in a hot bath—we have to acknowledge that such measures as immersion baths, particularly when combined with under-water douches at a higher temperature than that of the bath, and the use of media such as mud and peat, are of value. It might be possible to treat a group of patients suffering from osteoarthritis of the knees or hips and compare and contrast the results with those obtained in other groups treated by simple analgesics or by electrotherapy. The results could be difficult to assess if it were found that in one group of patients there had been a greater average loss of weight than in the others, because whatever else may be done weight reduction is essential in these usually overweight patients. With rheumatoid arthritis it would be, in my opinion, much more difficult to assess the results because of the natural or drug-induced variations in the activity of the disorder. Dr. Harris has told us of how in 1955 with Dr. Millard he made a comparative study of the treatment of the hands in rheumatoid arthritis. In three groups of subjects one group had no local treatment, and in the other two groups paraffin wax baths and packs were given. We know that they concluded paraffin wax baths are of little value in the treatment of rheumatoid arthritis. In this investigation they used the dipping and packing method instead of the original continuous immersion bath. Several years ago we used the dipping and packing method but quickly discarded it because our own observations suggested, and the experienced patients insisted, that it was not as effective as the original method. I should be grateful to know if Dr. Harris has pursued the investigation of the original technique as suggested in the paper as it would confirm or refute our clinical impressions.

When we were able to install a Hubbard Tank and certainly without being able to control our observations we were quickly of the opinion that those patients treated in it progressed more rapidly than those treated by other methods. There was no reason why we, the physiotherapists, or the patients should have been susceptible to suggestion because for the physiotherapists it meant more work and many of the patients had first to be persuaded to try it. The results were so clinically impressive and so increasing were the demands upon the tank that we asked for a deep pool. After four years' experience with the deep pool we have now asked for another.

Deep pools are expensive to construct and it has been difficult to obtain accurate estimates of the cost of our pool because it was built within the structure of an existing building and the main services were already easily available. Its construction and the provision of the filter plant and ventilation plant installations cost about £6,000. The estimated cost of a new department for physiotherapy and hydrotherapy which we are considering is £30,000 of which about half is for the proposed new deep pool with its heating and filtration plant and the necessary adjacent accommodation. We feel that the patients will derive as much value from one side of the building as from the other.

Last year the cost of maintenance of a deep pool was £700 but an adjustment of the heating apparatus has been made which it is estimated will reduce the annual cost to around £500.

In the pool patients are stripped so that all movements are continually under the observation of the physiotherapists and trick movements, for which most patients seem to

have an almost infinite inherent capacity, while more easily performed in the pool than on slings are more readily detected and corrected.

The relief from pain and diminution of muscle spasm on immersion in warm water are also important in that the range of painless movements is increased and this is not reproducible in any form of dry treatment. The adjustment and manipulation of the patients, particularly those who are most incapacitated and those who are obese, is much easier in water and much less arduous for those treating the patients. If we are to compare the value of a form of hydrotherapy with any other form of treatment we must take account of the amount of skilled supervision required and we have found that two physiotherapists working in a pool can treat in the same time about the same number of patients as they supervise in other forms of treatment. Incidentally, we have also found that a partnership of two physiotherapists working together in the pool is much more efficient and satisfactory than one working alone.

While individual muscles or groups of muscles may be re-educated by other means, co-ordinated movements to produce a natural movement such as arising from a chair are much more satisfactorily taught in water than on dry land. Such training may, in our experience, be relatively easily taught in water, difficult to teach on dry land and impossible to teach in the slings. Walking exercises without the use, or rather, the encumbrance, of crutches, are possible in water; and in the treatment of some patients suffering from the effects of poliomyelitis, we have found that walking exercises in water may be performed with the help of spinal and other supports which would otherwise have been impossible. Also, once accustomed to the pool, patients appreciate its value and although we have patients returning regularly and asking for further courses of treatment in the deep pool, we have not yet had one coming back and asking again to go on the slings.

For example one patient, a woman of 42, was first seen by me eight months ago. When 2 years old she had poliomyelitis affecting the lower limbs and she is later said to have walked with calipers, but at the age of 14 years she deteriorated and from her 18th year she had been almost completely helpless. She was in a spinal chair unable to move her head or to sit up, with a complete flaccid paralysis of the lower limbs, and only limited movements of both upper limbs were possible. Both the patient and the physiotherapist were enthusiastic to see what could be done in the deep pool, spurred on, I think, by my deliberately unconcealed scepticism. After a few preliminary immersions she was fitted with a polythene jacket and a head piece and began with much assistance to walk in the water. Then in water to axillary level she dispensed with the head-piece and recently she has been for a car ride sitting up with the head supported only by a pillow and able for the first time for over twenty years to look around her.

Another patient, a woman aged 49, was found eight years ago to have bilateral protrusio acetabuli with osteoarthritis of the hips and in the following five years her pain and incapacity increased although she was having regular treatment. Three years ago she began to have treatment in the deep pool and since, with four weeks' treatment each year, she has not further deteriorated.

**Dr. Harris,** in reply to Dr. Reah's question about paraffin wax baths, said that he and Dr. Millard studied only wax packs, and not baths. Continuous immersion in wax was the technique used when wax was first introduced, but for convenience most hospitals had replaced this by dipping and packing. This was the particular technique they had investigated; but continuous baths might be more effective. They themselves used continuous immersion baths as a routine for feet, but in practice continuous wax baths for the hands were uncomfortable as they usually necessitated patients sitting in awkward positions for thirty minutes.

## Methods of Measuring Pulmonary Diffusing Capacity and their Significance

By ROBERT MARSHALL, M.D., M.R.C.P.

*Oxford*

THE function of the lungs depends partly on their bellows action producing an adequate ventilation of the alveoli and partly on the ability of the lungs to transfer oxygen from the alveoli into the blood and $CO_2$ from the blood into the alveoli. This transfer occurs solely by diffusion and the gas with whose diffusion we are most concerned is $O_2$. The diffusing capacity of the normal resting lung is sufficient to supply about three times the normal resting $O_2$ uptake but this capacity has to increase in order to deal with the $O_2$ uptake required by even moderate exercise. Thus the reserve of the diffusing capacity for $O_2$ is small and if the diffusing capacity is impaired by disease respiratory failure may occur. $CO_2$ on the other hand diffuses over twenty times more rapidly than $O_2$ so that the elimination of $CO_2$ is never limited by diffusion, and $CO_2$ retention, when it occurs, is due to inefficient ventilation, not to impaired diffusion.

The diffusing capacity of the lungs for a gas is defined as the millilitres of that gas which can be transferred from the alveoli into the blood, per minute per mm.Hg pressure difference between the alveoli and the blood. The resistance to this diffusion is provided by the alveolar membrane which is normally less than $2{\cdot}5\mu$ thick and consists of the alveolar epithelium, a complex basement membrane and the capillary epithelium. The ease with which gas passes through this membrane, that is, its diffusing capacity, depends on the thickness of the membrane and the actual surface area separating the air and the blood. Any increase in thickness of the membrane or reduction in size such as would be produced by a reduction in the number of functioning alveoli or capillaries, will reduce the diffusing capacity.

The ideal measurement of diffusion to make is the diffusing capacity for $O_2$ but this method presents a number of technical difficulties. CO behaves similarly to $O_2$ in its uptake by the blood and many measurements of diffusing capacity are now made using small concentrations of CO which can be measured very conveniently with an infra-red gas analyser.

There are several differences in the behaviour of $O_2$ and CO which are of importance. First, CO is less soluble than $O_2$ in body fluids and the molecule is slightly smaller; the net result is that $O_2$ diffuses 1·23 times more rapidly through membranes than does CO (Fig. 1).

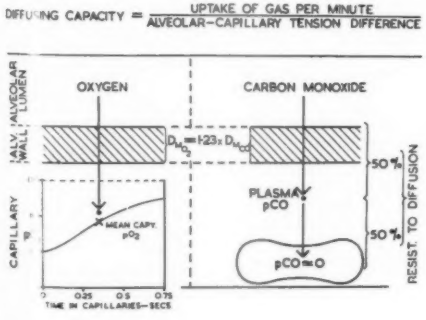

FIG. 1.—Measurement of the diffusing capacity for oxygen (left) and for CO (right). $D_{M_{O_2}}$ and $D_{M_{CO}}$ are membrane diffusing capacities for oxygen and CO respectively. $pO_2$ and pCO are the tensions of oxygen and CO respectively.

Secondly, the rate of combination of $O_2$ and hæmoglobin is three times faster than that o CO and hæmoglobin, but carboxyhæmoglobin breaks down very much more slowly han oxyhæmoglobin so that the carboxyhæmoglobin, once formed, exerts a negligible ack pressure of CO in the plasma. In calculating the diffusing capacity for CO, the capi lary tension is taken as zero and the uptake divided by the alveolar tension gives the diffu sing capacity. It is this ability to neglect the pressure of CO in the red cells that makes the c lcu-lation of the diffusing capacity for CO so easy and which has led to its widespread use. Forster, Roughton and others have been able to show that in normal subjects only a bout 50% of the resistance to the transfer of CO is due to diffusion through the membrane and the other 50% is produced by the slow rate of combination of CO with hæmoglobin. Thus the diffusing capacity normally measured with CO is not only a measure of diffusion thr ugh the membrane; it includes this extra resistance. The diffusing capacity for oxygen al o is not simply the diffusing capacity across the membrane. The proportions of the total resistance to diffusion offered by the membrane and by the red cells cannot be measured as in the case of CO but $O_2$ passes through the membrane 1·23 times more easily than CO and is taken up by the red cells three times more rapidly. Thus, if the resistance of the membrane is 50% and the resistance of uptake into the red cells is 50% of the total resistance to CO diffusion, then the corresponding proportions for $O_2$ would be 70% in the membrane and 30% in the uptake by the red cells.

## Methods of Measuring the Diffusing Capacity

(1) *The diffusing capacity for oxygen* ($DO_2$).—The factors to be measured are illustrated in Fig. 1. Although the alveolar gas is not usually uniform the mean alveolar oxygen tension can be calculated indirectly. The mean pulmonary capillary $O_2$ tension has to be calculated by Bohr's integration procedure from the mean alveolar $O_2$ tension, the $O_2$ tension at the beginning of the capillary, the tension at the end of the capillary and the oxyhæmoglobin dissociation curve. The tension at the beginning of the capillary can be estimated but the tension at the end cannot be measured because, before the blood can be sampled in the artery, venous blood may be mixed with it and this will produce a considerable fall of tension when the subject is breathing air. By breathing a low $O_2$ mixture this effect of venous admixture can be minimized and also the tension gradient between the alveoli and the end of the capillary is increased and the error of measurement is reduced. Thus measurement of $DO_2$ requires arterial blood and gas samples to be collected when the patient is breathing air and when breathing a low $O_2$ mixture. The tension of $O_2$ and $CO_2$ in the arterial blood have to be measured by the microtonometer technique developed by Riley—a technique which requires considerable practice and dexterity.

If the measurements are made on exercise it is found that the $DO_2$ reaches a maximal value at an $O_2$ uptake of about 1 litre per minute and this maximal $DO_2$ is considered to be of more value clinically than the resting $DO_2$ since at rest only a part of the lung's diffusing capacity for $O_2$ is being measured. The disadvantages of this method of measuring the diffusing capacity are that it takes a considerable time, the techniques are not easy and the need for an arterial puncture makes the method unsuitable for repeated use on patients. It is for these reasons that measurement of the diffusing capacity for CO has become popular.

(2) *The diffusing capacity for carbon monoxide* (Dco).—Two types of method are used, the single breath method and the steady state methods.

(*a*) *The single breath method:* This was first used by Krogh in 1915 and the technique has recently been improved by Ogilvie and others (1957). The subject breathes out as far as possible and then takes a deep breath of a mixture containing about 0·15% CO, 10% helium and 20% $O_2$; the remainder being nitrogen. The subject holds the breath for 10 seconds and then expires rapidly. The first few hundred millilitres of expired air are discarded and the remainder collected and analysed for CO and helium. The helium, which is not absorbed in the lungs, acts as a marker gas and makes it possible to calculate the initial concentration of CO in the lungs. The Dco during breath holding can be calculated from the alveolar volume and from the initial and final concentrations of CO in the lungs. This method is very simple and quick to carry out, it gives repeatable values and it does not require arterial puncture. Measurements on patients can be made only at rest.

(*b*) *Steady state methods:* The uptake of CO over a given time is measured as the difference in the amount of CO inspired and that expired: the uptake per minute, divided by the mean alveolar tension of CO, gives the Dco. Two methods have been devised and they differ in the ways by which the mean alveolar tension of CO is obtained. One method, described by Bates *et al.* (1955), uses the concentration of CO in the end tidal sample as a measure of the mean alveolar CO. This method is valid in normal subjects but it is not valid in patients, such as emphysema patients, who have unequal mixing of gas in the lungs. Experiments were carried out in which subjects breathed air containing a small amount of CO for several

minutes until they were in a steady state. End tidal samples were taken during several breaths and then, at the end of a normal inspiration, the subject expired fully into a tube of 1 in. bore and 16 ft. long in which the air was trapped and samples taken at intervals.

In normal subjects the concentration of CO in the samples at different parts of the tube, when corrected for the time of expiration, was uniform and was the same as that of the end tidal sample. In patients with emphysema, on the other hand, the farther the subject expired the lower the concentration of CO. The end tidal sample is higher than the mean alveolar CO and if it is used for calculation of the Dco, it will give falsely low values.

The other steady state method is that described by Filley *et al.* (1954). The mean alveolar tension of CO is calculated by assuming that the dead space for CO is the same as that for $CO_2$ and the $CO_2$ dead space can be calculated if the $CO_2$ tension in the expired air and the arterial $CO_2$ tension are known. This method, as originally described, requires an arterial puncture. In a modified method the arterial $CO_2$ tension is calculated from the mixed venous $CO_2$ tension, this being obtained by rebreathing a gas mixture containing approximately the same tension of $CO_2$ as that expected in the venous blood. This modification avoids the arterial puncture but it can be used only for measurements at rest.

## Comparison of Methods of Measuring the Dco

In normal subjects different ranges of values have been reported when using different methods of measuring the Dco and in patients with emphysema the steady state method using end tidal samples gives uniformly low results. With the single breath method about half the emphysema patients studied have a normal Dco. Some experiments were carried out to investigate these differences. The single breath method is usually carried out at full inspiration and this gives higher values than if the measurements are made at smaller lung volumes. In a series of normal subjects the steady state method gave values similar to those of the single breath method when the breath was held at about the functional residual capacity.

A series of patients with emphysema were investigated by the single breath method; some patients had normal and some had low Dco values. By the steady state method using end tidal samples all these patients had a low Dco. The results obtained by the modified Filley's method agreed fairly well with the single breath method when allowance was made for the smaller lung volume at which the measurements were made. The single breath and Filley's methods correct for uneven distribution of gas in the lung and the diffusing capacities of different parts of the lung affect the result equally, irrespective of whether they are under- or over-ventilated during normal breathing. If a part of the lung is poorly ventilated it will be able to take little part in gas exchange even though its diffusing capacity, as measured by these methods, is normal. The diffusing capacity of the lung measured using end tidal samples is not a measure of diffusion alone; it is affected both by diffusion through the membranes and also by unequal ventilation of the lung which gives a falsely high figure for the mean alveolar CO. For this reason low values are obtained in diseases in which the diffusion may or may not be reduced but in which the ventilation is very uneven, as in emphysema, and the results have been found to be of value in assessment of the prognosis of such patients (Bates *et al.*, 1956). But the measurement is not a measurement of diffusion alone and in such patients should not be expressed in the units ml. CO per minute per mm.Hg.

## Comparison of the Dco and $DO_2$ Results

We may decide, for technical reasons, to measure the Dco but we really want to know the diffusing capacity for $O_2$ and it is of interest to see how these two measurements compare. The Dco is a measure of the diffusion from the alveoli to the red cells and only half of this resistance to diffusion is in the membrane and the other half is due to the slow uptake by the red cells. In Table I the predicted values for $DO_2$ are compared with the measurements

Table I.—Comparison of the Diffusing Capacity for Oxygen and For CO

*Subject: R.M.* Diffusing capacity ml./min./mm.Hg

| | Single breath Dco | | | Predicted $DO_2$ | Approx. membrane $DO_2$ |
|---|---|---|---|---|---|
| | Total Dco | Membrane Dco ($DM_{CO}$) | $DM_{CO} \times 1{\cdot}23$ ($\equiv DM_{O_2}$) | | ($DM_{O_2}$) |
| Rest (at F.R.C.) .. | 28 | 48 | 59 | 20 | 26 |
| Rest (full insp.) .. | 32 | 51 | 63 | — | — |
| Exercise (full insp.) ($O_2$ uptake 2·6 l./min.) | 46 | 70 | 86 | 60 | 73 |

$DM_{CO}$ = membrane component of the Dco.

$DM_{O_2}$ = membrane component of the $DO_2$.

of total Dco by the single breath method and the membrane component using the single breath method at different $O_2$ tensions (Forster *et al.*, 1955). The membrane component of the Dco multiplied by 1·23 should give the same value as the membrane component of $DO_2$. I have not measured $DO_2$ so I have had to compare the Dco with the predicted values of $DO_2$ but a rough comparison can be made. The Dco and the membrane diffusing capacity for CO were measured at rest and the membrane Dco multiplied by 1·23 gives a calculated membrane diffusing capacity for $O_2$ ($D_{M_{O_2}}$) of 59 which is over twice the $D_{M_{O_2}}$ calculated from the predicted $DO_2$. On exercise sufficient to increase the $O_2$ uptake to 2·6 litres per minute the membrane Dco rises to 70 which gives a calculated $D_{M_{O_2}}$ of 86; this is in comparison with a predicted maximal $DO_2$ of 60 and a $D_{M_{O_2}}$ of 73 for a person of this size. At present we do not know the reason for these different results. One possible explanation is that the $DO_2$ measures the diffusion only into those capillaries through which blood is flowing at the time that the measurements are made; the Dco will measure diffusion into any capillaries containing blood irrespective of whether the blood in them is flowing or stagnant. If only about half of the capillaries have a normal blood flow through them at rest this could explain the different results obtained by the two methods; on exercise the blood flows through more capillaries and the two values approach each other.

To conclude, although the Dco does not give a direct measure of $DO_2$ the technical advantages of measuring the Dco usually outweigh the disadvantages, particularly since, in practice, the two methods usually run in parallel and for clinical purposes reduction in diffusing capacity can be shown quite adequately by measurement of the Dco.

The single breath method of measurement of the Dco gives the same results as the other CO methods and as it is the easiest method to carry out it is the method of choice for measurements made at rest. Measurements made on exercise minimize the technical errors of the steady state methods but except for this reason I know of no advantage to be gained from measurement of the Dco on exercise. The result depends on the rate of exercise and the maximum value for Dco is reached only at fairly severe rates of exercise in normal people.

# Oligopnœa [*Abridged*]

By P. Hugh-Jones, M.A., M.D., M.R.C.P.

*London*

The term "oligopnœa" was purposely chosen to mean an inadequate output of air from the lungs, just as "oliguria" is used for an inadequate or scanty output of urine.

*Some factors controlling ventilation.*—Before giving clinical examples of oligopnœa, their diagnosis and treatment, it is helpful to consider the factors controlling the normal "air output", or ventilation of the lungs. It is generally taught that this is chiefly regulated by the tension of carbon dioxide in the arterial blood. A rise of carbon dioxide tension stimulates the respiratory centre and leads to an increase in ventilation, while a fall in either oxygen tension or pH has a similar, though much less marked, effect. All this is undoubtedly true, but it is becoming apparent that nervous impulses from stretch receptors in the lungs play an equally, if not more, important role. Just as proprioceptive impulses from joints determine posture, reflexly in relation to muscle stretch, so these pulmonary stretch receptors regulate ventilation according to the degree of movement of the lungs. In disease, disturbance of reflexes from these receptors may become the primary mechanism which regulates ventilation, and this disturbance is readily accompanied by the sensation of "dyspnœa".

The significance of stretch receptors can most easily be demonstrated by a very ingenious experiment designed by Fowler (1954) which was concerned with the breaking point of breath-holding. It was held that the limit to voluntary apnœa was the rise of carbon dioxide and fall in oxygen tension in the blood causing extreme stimulation of the respiratory centre, and a number of papers had been published which defined these arterial blood gas-tensions when the limit to breath-holding was reached. Fowler got a spirometer and filled it with an "air" mixture containing oxygen and carbon dioxide at the same tensions as these gases would be in the blood at the limit to breath-holding. He asked a subject to hold his

breath for as long as possible and then to breathe in and out of the spirometer. Of course the subject's carbon dioxide tension then went on rising and oxygen tension falling but instead of feeling worse, he felt relief! After a while the subject felt uncomfortable breathing from the spirometer in this way, and was then asked to hold his breath again; soon he could hold it no longer and again he was told to breathe from the spirometer, and so on, until the total "breath holding" period was much prolonged. But from our point of view, the important thing is that every time chest movement was restarted relief was experienced, showing it was the lack of impulses from stretch receptors and not gas tensions which was of prime importance in the discomfort of breath-holding. And you can do this experiment now by simply stopping breathing; it becomes uncomfortable at once, long before there is a significant alteration in the gas tensions in the arterial blood.

It appears that if the stretch receptors either send no impulses or if they send excessive impulses the sensation is unpleasant. Excessive impulses occur when inspiration approaches the maximum possible depth (which again you can try now by taking in as deep a breath as possible). Excessive stretch of these receptors may be one of the many factors which appears to be responsible for the sensation of "dyspnœa" when ventilation reaches a certain proportion of the maximum possible ventilation, or maximum breathing capacity (Hugh-Jones, 1952).

Just as it has been shown by Fowler's experiment that breath holding is limited by stretch receptors rather than by blood gas tensions so there is increasing evidence that in some circumstances impulses from the stretch receptors, rather than blood gas tensions, regulate ventilation. These receptors send impulses from the lungs which are related to the work of breathing (Davies, Fowler and Lambert, 1956) and in disease states, for example emphysema, where the mechanics of breathing are disturbed and a given intrapleural pressure change may be responsible for a diminished air-flow in and out of the lungs, the patient may maintain a ventilation determined by keeping the work of breathing as low as possible, with his abnormal lungs, at the expense of maintaining normal gas tensions in his arterial blood. This is a common finding in emphysema where the patient readily complains of breathlessness if his ventilation is stimulated in any way (usually by exertion) and where the arterial oxygen is low and the carbon dioxide high when the patient is at rest. Yet such a patient, at rest, can often put his carbon dioxide tension back to normal by increasing his resting ventilation on command. Such patients Dornhorst (1955) has considered to be "lazy breathers". They are, in fact, in a state of chronic hypoventilation or mild chronic "oligopnœa".

*The effect of infection.*—The importance of mild chronic oligopnœa becomes much more apparent when the patient gets an acute respiratory infection. Any patient with a patchy bronchiolitis or bronchopneumonia has some parts of his lungs underventilated or even entirely unventilated, yet with blood still flowing in these areas. Thus, there is virtual "shunting" of venous blood into the arteries, in these underventilated areas. As a result of the increased carbon dioxide in the arterial blood, ventilation is augmented so that those parts of the lung in which air still flows are excessively ventilated. From them carbon dioxide can be eliminated, but the blood in them is already being fully oxygenated so their overventilation can only compensate for the rise of carbon dioxide in the arterial blood but not for the fall in oxygen caused by the presence of those areas of the lung with a normal blood flow, but reduced, or absent, air-flow. Hence the familiar picture of a cyanosed patient with pneumonia, breathing rapidly. If, however, the patient has altered mechanics of his chest as well as his pneumonia then, either because of excessive stimulation of the stretch receptors, or in some severe cases because of greatly reduced maximum breathing capacity, the ventilation is not adequately augmented and the patient becomes not only cyanosed but retains carbon dioxide. In other words, he develops acute oligopnœa, with relatively severe underventilation compared with his needs, even though he may appear to be breathing rapidly and hard. In such a patient, whose respiratory centre is no longer responding normally to carbon dioxide, the administration of oxygen for his cyanosis removes the remaining factor of anoxia, which was tending to maintain the little ventilation he had, so that his ventilation falls even further and leads to such high levels of carbon dioxide as to cause a comatose state to supervene on the disorientation from the previous lack of oxygen.

*Diagnosis.*—Clinically, the diagnosis of acute oligopnœa may not be easy; the mental state can be mistaken for that of a primary neurological condition such as a cerebrovascular accident, and the respiratory hypoventilation can be overlooked especially if there is rapid shallow breathing.

Just as the rise of blood urea is a useful confirmation of uræmia in states of oliguria, so arterial blood gas analysis confirms the carbon dioxide retention of oligopnœa. Another useful adjunct in diagnosis is to measure ventilation, just as one normally measures the urinary output for the diagnosis of oliguria; we use the very suitable anemometer designed

by Dr. B. M. Wright of the M.R.C. Pneumoconiosis Research Unit. It is small, virtually free from resistance, and can be used even with severely ill patients to chart their minute ventilation instead of simply charting respiratory frequency, which is, of course, not necessarily a reflection of the ventilation at all. With readings from this instrument, and the respiratory frequency, the alveolar ventilation can be calculated using an assumed value for the upper respiratory dead space. Then, the effects of oxygen and other therapeutic agents on the alveolar ventilation can be observed.

*Treatment of acute oligopnœa.*—Just as in oliguria arising from sulphonamides it is desirable to ensure a free passage for urine by flushing out the ureters by ureteric catheterization, so a free airway is the first essential in oligopnœa. In the patient with bronchopneumonia, secondary asthma is usually present, which is a major factor to air-flow obstruction. It is usually best detected by hearing the wheeze by auscultation over the throat, and treated by continuous aerosol inhalation of adrenaline or isoprenaline. This inhalation can be given at the same time as the oxygen which these patients badly need. We have seen patients in whom adequate aerosol treatment given with oxygen was itself enough to treat the hypoventilation. In all patients with central cyanosis from acute respiratory failure we give oxygen continuously and at a flow rate that is needed to remove cyanosis; if, on this regime, there is a tendency to acute oligopnœa, carbon dioxide retention, and drowsiness, then ventilation must be stimulated—either chemically, or if that fails, mechanically.

*Chemical stimulation of ventilation.*—Aminophylline (10 ml.) is given intravenously. It is a most useful drug in that it both acts as a central stimulant to ventilation and as an "antispasmodic" and we repeat it far more frequently than is customary, often two-hourly if that maintains adequate ventilation to prevent drowsiness from the oxygen and the patient gets no nausea with it. An alternative is intravenous nikethamide in similarly "heroic" doses of up to 5 ml. about two- or three-hourly depending on the clinical response. These injections, an aerosol of isoprenaline, and continuous oxygen successfully deal with the majority of patients who have acute oligopnœa on top of a chronic chest condition and literally save life while antibiotics have time to deal with the acute respiratory infection which usually precipitates this functional state. Nevertheless these patients are a serious medical emergency and if chemical stimulation is not completely successful and especially if abundant purulent sputum, or viscid secretion from status asthmaticus, prevents the maintenance of an adequate airway then we have no hesitation in performing a tracheotomy and using artificial mechanical ventilation.

*Mechanical ventilation.*—Tracheotomy is done under cyclopropane or intravenous barbiturate anæsthesia with Flaxedil as a muscle relaxant. With the tracheotomy tube in, adequate suction of bronchial secretions becomes much more practicable and a mechanical pump is used to provide the ventilation the patient needs.

A film, showing the first patient we artificially ventilated in this way, was projected at this stage:—

The patient was literally moribund, with cold extremities and feeble pulse, after a previous phase of high output heart failure of cor pulmonale. His respiratory rate of no less than 70 breaths per minute was associated with shallow abdominal breathing and negligible chest movement, and his severe oligopnœa was reflected by an arterial oxygen saturation 42%, carbon dioxide tension 74 mm.Hg, pH 7·32. Half an hour after tracheotomy blood analysis showed he had been over-ventilated by the pump because his carbon dioxide tension was then only 32 mm.Hg and his pH 7·63. Such over-ventilation can be dangerous and result in a further fall of blood pressure, especially if inadequate time is given in the respiratory cycle for venous filling of the heart. But after giving the correct ventilation his arterial blood was returned to normal (Fig. 1) and he was up and about in three weeks' time.

We find full humidification of gas going to the tracheotomy essential to prevent "crusting" in the trachea. If this is done there is little trouble with the procedure and simply by maintaining the arterial blood gases at normal through artificial ventilation, the heart failure disappears with an apparent lessening of the pulmonary artery pressure.

Usually a few hours on an automatic pump is all that is required to restore the arterial blood to normal and treat the acute oligopnœa though the tracheotomy may have to be maintained for a few weeks, not only to assist the efficiency of the patient's own ventilation, by reduction of upper respiratory dead space, but also to provide a means of sucking out secretions in patients who are not adequately coughing.

While the patient is anæsthetized and relaxed, any automatic pump in which the frequency and stroke volume can be altered is adequate if a cuffed tracheotomy tube is used. Occasionally a patient-cycled respirator is useful to "boost" ventilation later when the patient recovers consciousness, though it is rarely necessary.

We have had less success in using a patient-cycled positive-pressure respirator in the conscious patient as some American workers have recommended (Sicker and Hickam, 1956)

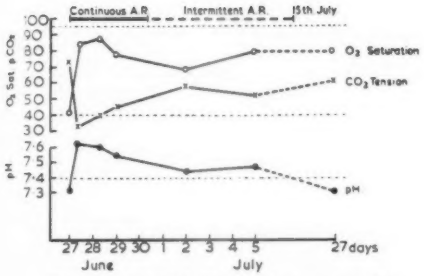

FIG. 1.—Arterial blood changes as the result of treating acute oligopnœa by tracheotomy and mechanical ventilation in a patient with advanced emphysema. (Continuous A.R.—automatic pump ventilation. Intermittent A.R.—patient-cycled ventilation.)

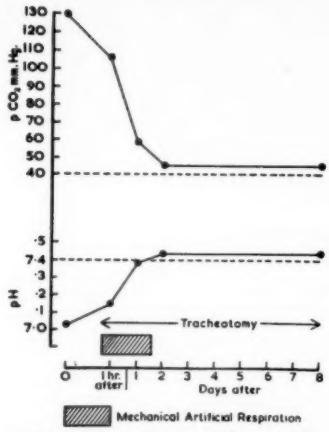

FIG. 2.—Arterial blood during treatment of acute oligopnœa from status asthmaticus.

for we find that oligopnœic patients do not tolerate a mask over their faces and, without a tracheotomy, their stomachs are inflated as well as their lungs! However, tracheotomy is a much simpler procedure than usually considered and really enables an adequate airway to be established. To "take over" a patient's breathing who is severely ill with respiratory failure by artificial ventilation under anæsthesia (when morphine or barbiturates can be given safely) is not only life-saving, but kind to a patient fighting for breath and oxygen.

*Indications for treatment of acute oligopnœa.*—An objection to the treatment of oligopnœa has been that it becomes merely a method of resuscitation of permanent respiratory cripples when it is applied in patients who may have chronic respiratory disease. Like using the artificial kidney in oliguria it is clear that mechanical ventilation with an "artificial lung" should only be undertaken for a temporary and potentially reversible condition. However, it is often extremely hard, if not impossible, to tell which patients have gross and irreversible emphysema when they are seen in oligopnœa from an acute respiratory infection. A demonstration of this is shown by an analysis made by Dr. W. B. Thomson of all the deaths over the last three years at Hammersmith Hospital clinically diagnosed as arising from acute respiratory failure in patients suffering from "emphysema" (Table I). Nearly a quarter had no material degree of emphysema at post-mortem examination, but died from a potentially reversible bronchopneumonia. Three or four years ago we resuscitated moribund patients with gross carbon dioxide narcosis from oligopnœa, who have had the subsequent years of comfortable and useful life.

TABLE I.—DEATHS FROM RESPIRATORY FAILURE IN HAMMERSMITH HOSPITAL

| Year | Nos. dying with diagnosis of bronchitis and/or emphysema | Nos. dying from resp. failure | Pathology: little or no emphysema |
|---|---|---|---|
| 1954 | 26 | 8 | 1 |
| 1955 | 25 | 10 | 3 |
| 1956 | 22 | 9 | 2 |
| Totals | 73 | 27 | 6 |

Thus, we tend to apply methods I have mentioned to all patients in whom there is even a slight prospect of relatively permanent success and then assess their lung function fully, as a guide to prognosis, on their recovery from the acute attack. Fig. 2 shows the progress of another patient who was admitted in status asthmaticus and who, after all the usual treatment had failed, including full steroid therapy, was referred to us by Dr. C. L. Cope. In her case the main problem was removing through the tracheotomy the almost

rubbery exudate which filled her bronchi; even after energetic suction quite a high pump pressure was needed to maintain her ventilation and reverse the severe oligopnœa which had caused such a dramatic change in her arterial blood gas tensions. But she made a complete recovery from this acute attack.

*Treatment of chronic oligopnœa.*—The treatment of mild chronic oligopnœa in emphysema is, like the emergency of acute oligopnœa, another worth-while field of therapeutic endeavour. Occasionally "lazy breathers" can be made to ventilate, with definite improvement in their mental well-being and a probable diminution of their chances of heart-failure from pulmonary hypertension, by the prolonged use of respiratory stimulants, including salicylates. But if such treatment is successful increased breathlessness from excess stimulation of their pulmonary stretch receptors may occur. There is probably a chance that our surgical colleagues could then help such patients by division of the nerve pathways in which these receptors run. But more research into the anatomical pathways of these nerves is much needed.

*Conclusions.*—The use of artificial mechanical ventilation in the ventilatory defects of poliomyelitis, tetanus, &c., is well established. We would like to see the treatment of acute oligopnœa in chronic respiratory disease become equally accepted. It is most rewarding. In fact tracheotomy and mechanical ventilation are rarely needed since energetic use of chemical stimulation of the respiratory centre together with antispasmodics deals with the majority of cases. But the diagnosis of acute oligopnœa must be made and adequate treatment given. We use oxygen in full amounts in all patients who need it and combat any tendency to carbon dioxide narcosis from oligopnœa by appropriate ventilation, achieved either chemically or mechanically.

## Mechanisms of Airway Obstruction in Emphysema and Asthma

By E. J. M. CAMPBELL, M.D., Ph.D., M.R.C.P.
*London*

NARROWING of the airways, particularly during expiration, is the most important physiological defect in the asthma, bronchitis, emphysema group of conditions. This expiratory obstruction is responsible for the limited ventilation and total gaseous exchange of which these people are capable. It is also responsible for most of the physical signs and for the reduced performance in such tests as the Maximum Breathing Capacity, Vital Capacity and Forced Expired Volume. The nature of the airway obstruction is poorly understood. The term "bronchospasm" is commonly used to describe it. Although I doubt if many of the people who use the word really believe that spasm of the bronchial muscles is the explanation of the airway narrowing, nevertheless little thought has been given to the number of ways in which the airways may be narrowed. Unfortunately, the common simple ventilatory function tests, although they provide good estimates of the severity of airway obstruction, do not distinguish between the possible causes. The mechanisms may be grouped as follows:

(1) Reversible disease of the airway, e.g. increased bronchoconstrictor tone.
(2) Relatively irreversible disease of the airway, e.g. chronic inflammation.
(3) Loss of elastic support of the airways so that they collapse during expiration.

I want to describe some studies which shed more light on these mechanisms. They were performed on normal subjects, on patients with asthma, and patients with emphysema. A full description of these experiments has been published elsewhere (Campbell, Martin and Riley, 1957), therefore technical details will be omitted.

The basic observation which provided the starting point of this study and which is to be found in earlier work concerns sequence of changes in intrathoracic pressure and rate of air-flow during a forced voluntary expiration (Fig. 1). If intrathoracic pressure is recorded from the œsophagus and rate of air-flow is recorded at the mouth during a forced expiration the rate of air-flow rises to a maximum value and then decreases while the intrathoracic pressure continues to rise. This observation suggested to us that there may be a maximum

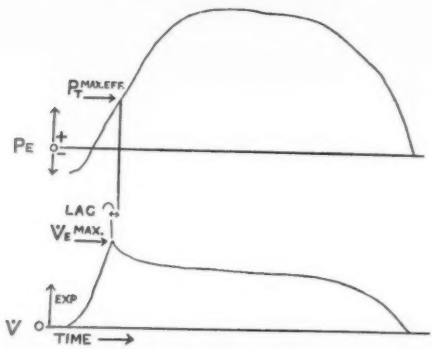

FIG. 1.—Intrathoracic pressure and rate of air-flow during a forced voluntary expiration. $P_E$, œsophageal pressure; $\dot{V}$, rate of air-flow (expiration upwards); $P_T^{MaxEff}$, maximum effective intrathoracic pressure; $\dot{V}_E^{Max}$, maximum expiratory flow rate (*see* text).

effective intrathoracic pressure ($P_T^{ME}$) associated with a maximum expiratory flow rate ($\dot{V}_E^{Max.}$). If $P_T$ rises above $P_T^{ME}$ the airways are narrowed by the high external pressure. This causes a marked increase in resistance and either reduces the flow rate or prevents it exceeding a certain value. We attempted to measure $P_T^{ME}$ and $\dot{V}_E^{Max}$ in 3 normal subjects and in two groups of patients. The first group consisted of 3 patients studied during attacks of asthma. They were chosen because between attacks they had no dyspnœa and had little or no detectable emphysema. The second group consisted of 5 patients with diffuse obstructive emphysema who had long histories of progressive dyspnœa. They were persistently breathless, and were studied after the inhalation of isoprenaline to minimize reversible bronchial narrowing.

In all 3 groups of subjects, in addition to $P_T^{ME}$ and $\dot{V}_E^{Max}$, the air-flow resistance during quiet inspiration was measured, that is to say the pressure difference between the alveoli and the mouth per unit rate of air-flow. This measurement should reflect airway narrowing due to such factors as bronchoconstrictor tone, œdema, &c., but not airway narrowing due to loss of elastic support because the airways are pulled open during inspiration; loss of elastic support only operates during expiration.

Table I gives the values we obtained at resting lung volumes. The maximum expiratory

TABLE I

| Subject | Flow resistance during quiet breathing. (0·5 l./sec.) cm. $H_2O$/l./sec. Mean | Range | Maximum expiratory flow-rate. l./sec. Mean | Range | Maximum effective intrathoracic pressure. cm. $H_2O$ Mean | Range |
|---|---|---|---|---|---|---|
| Normal (3) .. | 1·7 | 1·2– 2·0 | 5·4 | 4·5 –6·4 | 45 | 30–55 |
| Asthma (3) .. | 16·1 | 12·8–17·8 | 0·82 | 0·67–1·00 | 26 | 20–35 |
| Emphysema (5) .. | 6·6 | 3·2–14·7 | 0·96 | 0·58–1·25 | 9 | 3–24 |

flow rate is grossly reduced in both groups of patients to approximately the same levels. There are, however, important differences between the two groups; firstly, the flow resistance is much greater in the patients with asthma than in those with emphysema; secondly, the maximum effective intrathoracic pressure is much higher in the patients with asthma. It appears that in emphysema the flow resistance due to disease of the airways is not grossly increased but the airways become narrowed by relatively low external pressures, and therefore limit the flow rate that can be developed during expiration.

Fig. 2 is a diagrammatic representation of a simple model which can be used to study the factors affecting the patency of the airways during expiration. A mathematical analysis based on this model leads to conclusions consistent with our experimental findings. In Fig. 2 the airways have been represented as being in two stages, a proximal one whose walls have high rigidity and a distal one whose walls have negligible rigidity. The intrathoracic pressure is $P_TD$, the alveolar pressure is $P_{Alv}$ and the pressure in the lumen of the distal airway close to the junction with the proximal portion is $P_L$. It is assumed that an expiratory force

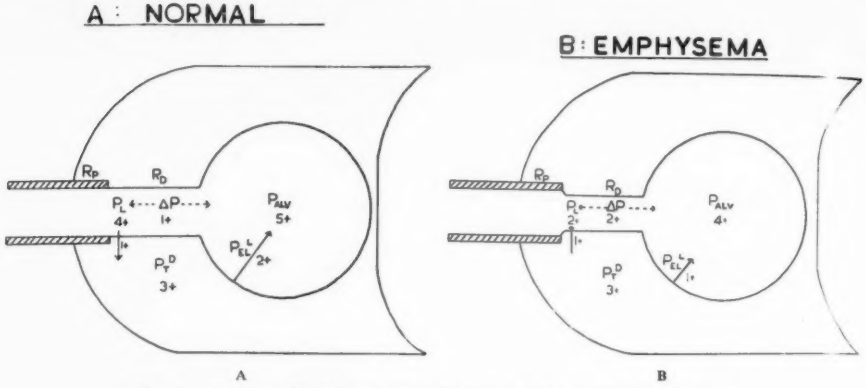

FIG. 2.—Factors affecting patency of airways during expiration (*see* text).

such as that provided by the contraction of muscles of expiration has raised $P_TD$ to 3+ above atmospheric. Fig. 2A represents a normal lung in which the elastic recoil ($P_{EL}L$) increases the pressure within the alveolus by 2+. Alveolar pressure ($P_{Alv}$) therefore $=P_TD+P_{EL}L=(3+)+(2+)=5+$. In Fig. 2B which represents an emphysematous lung the elastic recoil is only 1+ and $P_{Alv}=P_TD+P_{EL}L=(3+)+(1+)=4+$.

If in the normal lung the resistance in the distal airway is so small that the pressure drop ($\triangle P$) from the alveolar space is only 1+, then $P_L=P_{Alv}-\triangle P=(5+)-(1+)=4+$. The pressure difference across the wall of the airway is therefore $P_L-P_TD=(4+)-(3+)=1+$. In the emphysematous lung more resistance in the distal airway is assumed so that $\triangle P=2+$, and $P_L=P_{Alv}-\triangle P=(4+)-(2+)=2+$. In these circumstances the pressure difference across the wall of the airway is $P_L-P_TD=(2+)-(3+)=1-$. This is the same as a pressure difference of 1+ tending to narrow the airway.

If one neglects additional pressure effects caused by the properties of the wall of the airway itself, the pressure difference across the wall of the normal airway will cause it to remain open whereas in the emphysematous lung it will cause narrowing.

The mechanisms responsible for the expiratory obstruction in asthma will not be discussed partly because the possibilities are more complex and partly because my main aim is to suggest a method of approach to these problems rather than to present a complete analysis.

In spite of the initial impression of complexity this approach does suggest that much greater discrimination between mechanisms of airway obstruction is feasible.

## DISCUSSION: THE MANAGEMENT OF THE HOPELESS CASE

**Dr. Ronald Gibson** (Winchester):

I am told that in ancient Babylon it was against the law for doctors to attempt to treat hopeless cases. To-day, as I offer a twentieth century family doctor's conception of the management of these cases, I view with some envy the position of my Babylonian predecessor.

"Hopeless" patients are those of any age group who are suffering from a disease or state which we, with our present knowledge, regard as incurable. At any moment, with increasing knowledge, one or more will be struck off the list. In other words, the incurability or hopelessness is used by us as an expedient pending further research, and there is no reason therefore, why we should not adopt a positive approach to those patients from the very beginning, and follow the excellent example of the Bishop of Durham (Harland, 1957) who said of the dying that they must never be deprived of their last joy on earth—which is hope.

Hope is a state of mind in which one expects confidently that what one desires will come about—it is confident anticipation. Until a certain stage is reached in the lives of these patients for whom we have so far failed to find a cure they are confident of their return to a state of health comparable to that of the average individual they see around them. They are, in fact, hopeful. When they begin to die their desires change, so that they look forward with confidence to their dying and to this world's release from their adversities. They are still hopeful.

This approach, of course, could be called academic and unreal. But I must emphasize at the outset that the theme of care (so far as I am concerned) must be played in a major key of which the dominant note is hope. The basic principle is that the patient's expectation, whether of life or death, must be created by the doctor, nurtured and maintained by him, and guided by him so that hopelessness (whilst it may conveniently appear as the title of this debate) never enters the patient's mind.

To pigeon-hole or catalogue these cases would, or course, take a book in itself. Hopelessness may be diagnosed at birth or at any time within the next hundred years. Care may extend over hours, days, months or years. So that some limiting definition is necessary.

### DEFINITION

I. Gavey (1952) says that the term "hopeless" implies that the patient suffers from "a disease or state from which recovery is beyond reasonable expectation". This classification could be broken down, I think, by dividing such cases into two:

(1) Those whose expectation of life has been materially diminished by reason of the disease from which they suffer, and

(2) Those who, whilst suffering from a disease or state from which recovery is beyond reasonable hope, will not suffer any diminution of their expectation of life because of it.

Having defined hopelessness I must now explain what I mean by "care".

II. Care implies *total* care, that is to say I am looking upon the patient as suffering from more than just a specific illness. I am acknowledging that chronic illness (as Jerome Tobis (1955) emphasizes) has a social as well as a biological character, and therefore the efforts of the doctor and his helpers must be directed towards the maximum function of the patient in all fields—physical, psychological, vocational and social. I acknowledge, too, that this is no easy task—for care must not continue for a limited period and then be allowed to lapse because of diminishing interest, lack of new ideas, or over-work. Care that is allowed to regress is worse than no care at all.

How does care begin? How is the degree of care assessed? Obviously the first factor to be considered is the disease from which the patient is suffering, into which category it falls and the degree of disablement it is causing. Symptomatic treatment can then be instituted. This is care of the disease and not of the patient—the latter will follow.

Starting in this way the doctor gets to know his patient, the patient's family and his environment, and he can arrange all three into the pattern that he knows will be most suitable for the long time ahead.

I propose, therefore, to start with the care of the environment, to proceed from there to care of the relatives, and then to care of the patient.

### The Environment

The design of the environment depends on two major factors at the outset: the home background and the financial status. The Welfare State has influenced both of these.

In the first place it has raised the standard of living of the population, eliminated gross poverty and improved public health education. Thus the State doctor, under the National Health Service, can enter practically every home in the country, and can take with him the State nurse, the health visitor, the home help, the social or welfare worker, without any thought for the family's income in pounds, shillings and pence.

Nowadays the degree to which these people can influence the environment, therefore, depends more on whether the patient is surrounded by a loving and responsible family than upon the financial or social status of the family, and it is unfortunate that the State, in taking so much obligation upon itself for the welfare of society has, at the same time and inevitably, lessened individual responsibility towards the family. Without this individual responsibility even a healthy family may break down, and it is certain that one which includes a chronic sick person will tend to push the responsibility for care and management on to the State, and the patient's environment will be that of a chronic sick hospital or nursing home.

Attention to environment obviously involves in the first place a rearrangement of the house—not always easy to bring about at once—often a great deal of suggestion is required over a long period. A bed-room downstairs may mean considerable sacrifice to some families; with others there will be room to spare. Some patients—particularly the older ones—fear the ground floor at night.

Such a move may also necessitate the provision of lavatory accommodation downstairs, the elimination of steps in and outside the house, the widening of doors and gates, and so on. In this re-educating and conditioning process the health visitor can be a great help to the doctor, and also in introducing the Daily Living Department to the family.

There is, unfortunately, no time to enlarge on the work of this department. So many "gadgets" can be invented and provided. Suffice it to say that almost any individual's needs can be supplied.

The environment plays an important part in building up the pattern of the patient's day – not only to keep him amused and occupied in gainful occupation, but also to impress him continually with the true fact that he can still be a useful member of the community.

Diversionary activities designed to take the patient's mind off himself and his illness include the television and wireless, cross-word and jig-saw puzzles and various card games; the encouragement of hobbies, such as carpentry, painting and needlework, writing and stamp collecting. All these fall within the province of the social and welfare workers, the W.V.S. and the Red Cross. Not to be forgotten also are visits from the librarian and, perhaps most important of all, the arrangements which must be made for continuing the patient's education, particularly along the lines necessary for possible re-employment. Thus it can be seen that *people* play a prominent part in the make-up of the environment. Dr. Alfred Worcester (1935), for example, reminds us of the importance of introducing new friends to the patient, of ensuring his association with young people and of maintaining at all costs his personal vanity.

### The Relatives

To turn to the relatives. I am reminded of the young general practitioner who, after a misdiagnosis and subsequent death of his patient, felt it incumbent upon himself to apologize to the relatives for his shortcomings. They were quick to reassure him. He was, they said, the only one who had given them any hope.

Where possible it should be left to the family doctor to deal with relatives. This is not intended as a slur on the consultant; I always pity him when he has to interview relatives in hospital—he has probably only known the patient for a few hours, and he meets the relatives face to face for the first time outside the ward. How can he possibly know how to arrange his story—how much to tell and how much to leave out—and, particularly, how much of the future to predict? We have to deal with two types: those who are suddenly faced with an acute crisis—such as the onset of poliomyelitis in a child; or those whose lives have been gradually conditioned to a change in the family environment—such as would be brought about by the progress of an inoperable carcinoma in an elderly and dependent relative. The latter change, being slower in development, is more easy to manœuvre, but both groups depend for their management on the personality and outlook of the particular relatives, and it is impossible to assess this at a first meeting.

It is, therefore, the G.P. with a knowledge of the family extending over years, who best knows how to manage these people. Mismanagement of relatives means mismanagement of patient, for the hopeless case is going to be far more dependent on them than on the doctor or his helpers—it is therefore vital that the right outlook should be adopted from the start.

Recently, a patient told me, quite calmly, that she had had her eyes tested and had been

told to go home and learn braille, for within two years she would be blind. I winced at the abruptness of this but she seemed quite contented and determined to make the most of her environment for as long as she could see it (she was already making a note of things she had never seen before, and storing them up so that she would remember them when she could no longer see them). Not so her relatives. They had been given an even blunter prognosis. Their lives were going to be changed by this failing vision to a greater extent than the patient's, for it is one thing to go blind and another to have to care for the blind—and for an indefinite period. A patient going blind is, after all, a hopeless case according to our definition, although the expectation of life may not be diminished, and this is *not* the way that the family doctor would choose to set about preparing patients and relatives for a changing scene.

One talks of dependence of patients on relatives. If anything a more tragic situation develops when relatives become dependent on patients. The progress of a chronic illness may bring with it the development of a selfish or possessive attitude on the part of the patient towards those in closest contact with him. The family doctor must watch out for this and do all he can to stamp on it before it becomes irreversible. I remember one devoted family, all of whom were wage-earners until one sister developed Parkinson's disease. Another sister stayed at home to look after her whilst the remaining two sisters and one brother continued to maintain the family exchequer. It was all done with the best possible intentions. Now the one sister is irretrievably bound to the invalid who "cannot live without her", and every bit of strength is being sapped out of her as the years and the disease proceed very slowly to take their toll of the patient. Care of a hopelessly sick person is also the responsibility of the family as a whole and must never be delegated to one individual member of it.

If it takes an experienced G.P. to lead relatives into the atmosphere of chronic sickness without undue trauma to themselves or to the patient, it requires even greater tact and knowledge to guide them through the phase when a hopeless life gradually proceeds towards its end. It is difficult to understand that those who immediately care for a chronic patient may become so attached to him that they will struggle against the only possible and, indeed, only happy conclusion. This struggle can be dangerous because it may be transmitted to the patient, and what might have been a tranquil ending to a life becomes one of bitter argument right up to the last; it may lead to resentment against the doctor, his helpers and family friends, to the employment of all sorts of unorthodox methods of treatment and even, finally, to a turning away from the God who allowed death to separate them from their loved ones.

## The Patient

We have now discussed the inauguration and supervision of the programme which is to absorb those who make up the most intimate circle around the patient—the supporting cast, as it were. We have arranged the environment to suit the particular patient—in other words, the scene is set. We must proceed to a consideration of the management of the patient himself—the leading actor.

I am convinced that from the very outset it is the family doctor's duty to encourage the patient in an aggressive attitude to his disease. Such an approach has, in fact, been emphasized recently by Dr. Bodley Scott (1957) who, in an address to the B.M.A., said that the patient's happiness is best served by encouraging him in an aggressive attitude towards his disease—to keep at work and to live a normal life until physical disability makes it impossible. Along with this, as Dr. Bodley Scott says, must obviously go the exploitation of every available means to procure even temporary and partial remission of the disease. Both of these—the aggressive attitude and the attempts at treatment—are calculated to encourage the patient to a positive attitude towards his illness—in other words, a hopeful attitude.

The essence is that the onset and progress of a disease must never be permitted to interfere with the patient's love of life. He may love it from a bed or a chair, a bedroom or a ward, but the changing circumstances of his life must not interfere with his devotion to it. Tolstoy (1868–69), it will be remembered, said that the most difficult thing—but an essential one—is to love life. To love it even while one suffers, because life is all.

Which leads me to my next point: I have often found it useful to remind newly diagnosed hopeless patients that, if they come to think of it, life is always a struggle—even for the apparently healthy individual, and either mentally, physically, or both. The onset of an incurable disease may add to the struggle but, even so, may not bring it up to the level of that suffered by some people who, though apparently healthy, yet are constantly fighting some unseen physical or mental disability which they dare not share with anyone.

The onset of care, then, or the first phase of care, revolves round an assessment of the personality of the patient and of his ability to tackle the future; helping him in the first few weeks to recover (or, if possible, to enhance) his love for life and his determination to go on living; enabling him quietly to settle down in his new environment and to accept his relatives, the doctor and his co-workers in their new status; and, finally to start him unobtrusively on the routine of his new daily existence.

### The Routine of Daily Existence

It is this "routine of his new daily existence" with which we are now concerned. Obviously it would be impossible to detail the whole list of apparently hopeless cases in order to outline the specific treatment for each. I am going to concentrate, therefore, on what I call "average" care, which is really the build-up of care ready and waiting for all new hopeless cases, one or other end of which may have to be modified to suit a particular case. When first discharged from hospital and waiting for the family doctor to call the patient will nearly always remain in bed. Even though he has been up every day in hospital he will keep to his bed at home until the G.P. confirms that he is the same patient suffering from the same disease, and therefore, liable to the same treatment at home as in hospital. Rather like a ship that has been prepared for launching he remains unmoving until the home doctor presses the switch!

This is not altogether a bad thing, because the first visit must include a preliminary chat. Even though he has been in hospital there will be a lot he still requires to know. Everything possible must be carefully explained to him with mingled sympathy and honesty, and then he must be told of what has been arranged for him at home and of how he is expected to proceed. A word of warning here: he may not have been told of the hopelessness of his case. It is disastrous for the family doctor to assume that the patient has accepted that he is suffering from an incurable disease when, in fact, for one reason or another, he has been carrying on under the assumption that he is going to get better. The contrary is, of course, equally true—when the patient has prepared himself for the inevitability of his future and the family doctor optimistically starts off on the lines that no effort will be spared to get him better. Both can happen if the first talk is not carefully guided and controlled by the doctor.

### Physiotherapy

When possible, then, the activation of the patient proceeds from the first visit of the doctor, bed-rest being carefully balanced against over-exertion. With this goes the arrangement and management of exercises, requiring the active participation of the patient and having the additional advantage of helping to take up a good part of his day. Additional aids and self-help devices come in here, and physical rehabilitation may have to include the advice and assistance of various specialists—the specialist in physical medicine, the orthopædic specialist, the neurosurgeon and the plastic surgeon—all working with the family doctor towards the three major aims described by Jerome Tobis (1955): the relief of pain, the increase in range of motion and the increase in motor power. It is the G.P. in the first place who must recognize the need for the appropriate specialist, and call on him.

### Chemotherapy

Chemotherapy (or treatment by drugs) clearly has an important place in average care—if only for the mouth, the bowels, the skin, for pain and for sleep—apart from any specific treatment.

As an analgesic I still use the pot. bromide and aspirin mixture[1] I used in hospital, with or without the addition of codeine phosphate (omitting any reference to possible constipation with the exhibition of codeine!). Largactil, Physeptone and pethidine follow in that order. I find Largactil an immensely useful drug, especially for the vertigo and/or nausea of the senescent. For sleep, "Mist three fifteens,"[2] Soneryl, "Spansules" of phenobarbitone and Omnopon furnish all I need to ask, and here I must say that I cannot subscribe to those who write of the necessity for increasing doses of morphia in treating the dying. I have never had to resort to this.

For the skin, in addition to the nurse's routine care, Compericum has a definite place, and when the skin breaks down I always first use an ointment[3] to be found in the St. Mary's Hospital Pharmacopœia—I know it must be good because of the number of nurses who insist on using it.

I find that constipation usually responds, at any rate in the first place, to a compound paraffin emulsion night and morning, with or without the addition of liquid cascara in varying amounts to the evening dose. Mist. magnes. hydroxidi with liquid paraffin is also useful, and I find Senokot of great value.

Urinary and fæcal incontinence are distressing complications and between them are more likely than almost anything else to cause the breakdown of home care (except, possibly, insomnia and the constant need for care at night). In treating these one has to rely on good

[1]Pot. bromid. 7½ grains, codein. phosphat. ⅛ grain, mist. ac. acetylsalicyl. *ad* ½ ounce.
[2]Tinct. opii 15 minims, pot. bromid. 15 grains, chloral. hydrat. 15 grains, aqua *ad* 1 ounce.
[3]Acidi borici 15 grains, olei eucalypti 15 minims, bismuthi subnitratis 60 grains, zinci oxidi 1·0 grains, oleum ricini *ad* 1 ounce.

nursing discipline combined with regular habits, encouragement and the application of almost eternal patience.

There is so much more to chemotherapy than I have either the time or the expert knowledge to include.

### Diet

Over-eating must not be encouraged, but, on the other hand, so many patients, particularly the elderly, have such poor appetites that there is little hope of correcting metabolic deviations and it does seem that no amount of vitamins, calcium, androgens and/or œstrogens can overcome the defect. No harm can come from giving in to particular cravings, and there is no point in forcing a patient to eat food he heartily dislikes simply because the relatives think it is good for him. I have found Cytamen, Becosym and Complan useful adjuncts.

### Social Therapy

I have already discussed this fairly fully under "the environment".

The social worker is an invaluable member of the doctor's team. It is beyond the time, and, I imagine, the ability of the average family doctor to analyse the vocational capabilities of the patient, the capacity for further education or for a return to some form of employment. The analysis *must* be made, for it will be remembered that we must impress the patient with his continued importance to the community at one level or another.

Work need not necessarily be for financial gain. It may merely be for mental relaxation; as a time-passer or (perhaps most important of all) as a means of doing service to others in the community.

### Spiritual Therapy

It has always seemed remarkable to me that most patients automatically regard their doctors as atheists or, at best, as agnostics. Many times I have regretted that a patient should feel it necessary to apologize to me for the suggestion that he might get some help from a priest—and would I mind if he tried. Worse still is the surreptitious consultation between patient and parson without letting the doctor know, in case he would be offended or would not understand.

I include spiritual therapy automatically in my care of the hopeless case, and only if I receive a dogmatic refusal of such help do I pass over it. By this I do not mean that I encourage the patient to consult *any* clergyman. If he definitely states that he would like to see a particular one I ask if I may contact him. With this permission I tell the parson the medical aspects of the case and ask for his co-operation.

If I am *not* specifically asked for a particular priest I must say that I prefer my own choice. Where I come from, of course, they can be seen wandering about in prides, and it is not difficult to find one to help in almost any situation; but I have learned that, like specialists in other fields, each tends to show a partiality for a particular type of patient. I need not say how much nicer it is to be able to call in the parish priest, since he exercises the same authority in the spiritual field as the family doctor does in the medical, but it is not always possible.

I am convinced that a patient on whom it is not possible to apply spiritual therapy is missing a major part of his treatment, and the lack of this vital constituent of total care makes the remainder far more difficult to apply and far less effective in result.

One cannot leave this aspect of care without touching on the tragic move so often made by patients or their relatives who, as I have already said, in desperation at the hopelessly inevitable nature of the prognosis, proceed to employ some peculiar and unorthodox "spiritual aid", of which there are so many different varieties. That some of these so-called spiritual healers, or the like, are honest in their beliefs and in their desire to help there can be no doubt, but others merely exist in order to play on the feelings of, and to make money out of, the hopelessly ill. All one can do is to wait for the anti-climax and, when it comes (as it inevitably must) receive the patient back into the fold without recrimination. Argument in the beginning or recrimination at the end may bring about a change of doctor, and with this a possible change in the routine of daily life and of treatment. This should be avoided at all costs (even that of the doctor's pride) for enough damage may well have been done without this additional risk.

### Psychotherapy

This undoubtedly has a place in the care of the hopelessly sick. I am still middle-aged enough as a family doctor to believe that, other than in exceptional circumstances, I ought to be able to manage my hopelessly sick patients as though psychiatrists had never been invented. I hope that too many of my patients have not suffered for my obsession in this respect although, even so, I fear that I should remain unrepentant.

### The Phase of Dying

In the care of the patient when dying, all these therapies still have their place. Gradually chemotherapy and spiritual therapy will take precedence over the others. The fundamental aims at this stage are the banishment of pain and anxiety. A judgment of the patient's personality and beliefs must sway the doctor in his decision as to when, if at all, the patient is to be told that the last stage has been reached, and how to tell him; often the priest can and should do this last sad office.

We all of us know how peaceful death can be when it is faced without fear, and equally how delicately the process of dying must be handled by all concerned so that nothing is allowed to ruffle the calm or break the stillness. William Hunter said "How easy and pleasant a thing it is to die"—and this is true.

Once Sir William Osler was visiting a dying child and knowing that the end was near he picked a beautiful red rose from his garden. He took it out of his pocket in the sick room and told how he had watched the last rose of summer growing in his garden and how the rose had called out to him as he passed by, saying that she wished to go along with him to see his "little lassie". The little girl understood that neither fairies nor people could always have the colour of a red rose in their cheeks, nor stay as long as they wanted in one place.

Death is not a hopeless thing; nor are the dying without hope. Therefore, if for no other reasons, our care of these patients is infinitely worth while.

**Dr. C. J. Gavey** (London):

There is a growing medical and lay interest in the problem of the hopeless case. I tried to assess the situation in 1950 (Gavey, 1952) when I was struck by the paucity of literature of a type that was readily available; but since then statements have been made in other Sections of this Society, notably in the Section of Medicine on "The Management of Advanced Cancer" (1955) and in the Section of Surgery on "Palliation in Cancer" (1955): Medical books have appeared such as "Should the Patient Know the Truth" edited by Standard and Nathan of New York (1955) and very recently Davidson's "Medical Ethics" (1957) containing contributions pertinent to our subject. Laymen have also written of their experiences as sufferers from dread diseases, e.g. Evans (1952) from epilepsy, Opie (1957) on poliomyelitis and Hession (1956) on cancer of the colon with colostomy, to mention only a few. Last year the Archbishop of Canterbury collated data on Divine Healing (1956).

Television has given a great deal of information to the general public as to what can be done for cancer and certain types of heart disease, and we cannot stop thirst for knowledge on these matters. What is happening in America is more slowly happening here. I mean the study of the facts of disease by all and sundry. A degree of impatience is appearing in people who want to know the why and wherefore, and up to a point they have a right to this information. In other words they can read and learn of the scientific aspects of medicine; but its method of application rests on a higher plane and requires the long arduous training of a doctor who must retain independence if his best is going to be good. At no time has the doctor's prestige been so much in the balance, but we need have no fears if we give judgment based not only on knowledge but also on feeling. Judgment is difficult and increasing knowledge brings its own problems: a hundred ways of investigation bring a hundred ways of going wrong, hence the need for a balanced attitude to investigation, in teaching and in practice, based on the highest integrity, and a profound respect and awe for body and soul. Sherrington (1951) in "Man on his Nature" put it to us that "human doings, human feelings, human hopes and fears move man as does nothing that is not human . . . We have, because human, an inalienable prerogative of responsibility which we cannot devolve, no, not as once was thought, even upon the stars. We can share it only with each other". Science, wonderful though it is nowadays, and worthy of meticulous attention, provides no short cuts to assessment of the patient as a whole; this can only be achieved by careful study at the bedside as of old. Graves once said "Genius will not compensate for lack of clinical study at the bedside".

Laymen are gradually acquiring a knowledge of survival rates instead of death-rates and

it is proper that it should be so, for anyone who is stricken with a killing disease will tend to think of the possibility of recovery rather than the inevitability of death and so from the start a valuable defence is set up. Initial fears from increased knowledge are giving way to the feeling that something substantial can be done. Have I a chance? says the patient. In order to be able to answer this with the confidence that the patient can detect, we should have in mind the cures or arrests that we have known. Men will fight against great odds, but not for so long if defeat is thought to be certain. Thus the patient, now better informed, plays an increasing part in the management of his disease but at the same time our responsibility becomes infinitely more exacting.

Certain *religious considerations* are relevant to our work as doctors. When the situation seems hopeless, nothing remains to solace except Faith, but Faith can be like a ". . . promontory of the sea, against which, though the waves beat continually, yet both itself stands and about it are those swelling waves stilled and quieted" (Marcus Aurelius). Most patients are not afraid of death but are reluctant to die. I think that applies to some atheists and to religious folk alike. The reluctance to die has largely to do with the welfare of remaining relatives and the instinctive will to live. In this country it is now seldom that we meet patients who dread death because of possible utter damnation hereafter but perhaps the majority have qualms at some time about their position in after-life, and would welcome an opportunity of improving at the last their relationship with God. Though we would wish that all had given this communion with God a life-long application, it is not practical to assume that. My view is that the doctor is not expected to minister himself but he is expected to see that spiritual help is available and to co-operate readily with the priest. Though there is a growing mutual respect, I think it is common for the clergy to be reluctant to approach the doctor, and the doctor the clergy. Then the help of an intermediate person, the Sister in hospital, or a friend or relative in general practice, is appropriate and welcome to all parties. It is very doubtful whether anyone should be allowed to die of chronic disease without some warning of that possibility, at least at the very end. We know that Roman Catholics have unwavering views on the utter necessity of preparing a patient for death and anyone with religious feeling would I think desire everyone to be prepared; but as doctors we have no prerogative to decide this issue categorically, but simply to co-operate wholeheartedly with the clergy in satisfying the needs of our patient. I would emphasize here that the last Sacrament does *not* remove all hope. It is for those in *danger* of death, not necessarily of certain death. In regard to the patient who is actually dying, I believe he is more often aware of the ministrations at the last, than the doctor might think on medical grounds. A doctor is recognized as one who is unbiased as to race or creed, which is perhaps the reason for the common unjust accusation that doctors are lukewarm in matters spiritual. Indeed many, possibly most, doctors rely consciously on religious beliefs as a source of strength in their arduous work.

Courage is a virtue with which we are very variously endowed and we must recall that disease may in some cases undermine courage by reason of its nature or severity, especially when prolonged, and associated with distress in the family. Let us remember the experience of our Lord: "He was withdrawn from them a stone's cast and kneeled down and prayed: 'Father, if thou be willing, remove this cup from me: nevertheless not my will, but thine be done.' "

*Telling the patient.*—The Hippocratic Oath charged us to "follow that system or regimen which according to our ability and judgment, we consider to be for the benefit of our patients and to abstain from whatever is deleterious or mischievous". In the doctor-patient relationship the patient has implicitly charged the doctor to give him the maximum help in combating the disease, and as we doctors see it, the patient has in his own interest, implicitly left this problem of telling to the doctor's judgment. It is a human right to know the truth about oneself, if the truth be known, but it is not incumbent on anyone necessarily to exercise that right. Most doctors say that for themselves they would wish to know the truth, e.g. Osler, Cushing and others. The doctor must be sure of his facts yet prognosis is difficult and full of pitfalls. The slightest doubt regarding diagnosis and prognosis will indicate the postponement, if possible, of intimation of the state of affairs until time has clarified the position medically, and prepared the patient for bad news. All of us could quote examples of mistaken prognoses, but if only we remain aware of our fallibility we are not likely to do harm in this connexion, especially if, when telling our patients, we include what we don't know. More patients would seek the truth if they realized that terminal illness is not as a rule attended by acute suffering. In most diseases a toxæmia supervenes which dulls the mind and favours a peaceful exit. More patients would ask if they had the opportunity, hence the importance of regular visiting. Some do not want to know the disease at work—simply their expectation of life. Others only want the sympathetic ear of a responsible person. A relative should know the position. It is not infrequent for the relative to ask that the patient be not told. This may be reasonable but our prime duty is to the patient.

The patient who obviously knows the truth may never seek to talk about it and a mutual understanding rests on this. There is the occasional patient, rare in my experience, whom one feels should not be told lest the truth harries him and his family. The maxim to do no harm applies here, but it is usually possible to advise against undertaking important commitments simply on grounds of ill-health. Self-deception is sometimes fostered and it might be unwise to intrude at that moment unless some important family or public interest demands attention to his affairs. There is something to be said for the method of telling whereby a relative or close friend takes that responsibility for as Munk (1887) said "they do so without destroying his hopes, for the patient will still believe that he has an appeal to his physician beyond their fears".

Perhaps half the population still believe that we usually avoid the truth. A few venerable physicians and surgeons have told no one of a fatal issue if they could possibly avoid it. I have told many and never regretted it, but I have tempered the truth with such solace as I could muster, never closing the door until the very end, for as Ogilvie (1957) has said: optimism is the greatest analgesic and hope is the most certain tranquillizer. In a patient with cancer for instance, it may greatly facilitate treatment if he knows the rationale of it but once the position has been stated there is no place for reiteration. I have known some who, having known the truth did not finally accept it and thus they found strength to go through their treatment. Mystery, fear of the unknown, may sap the patient's strength and undermine his morale. I have not met an example of suicide in a patient whom I have told, but I know that very rarely it does occur.

I would say without hesitation after years of study of this problem that there is more to be gained than lost by adopting the attitude that enough should be said to satisfy those who would wish to know the truth. Much depends of course upon the way and time of telling, but I have been astonished at the courage, determination and final resignation of so many patients and my admiration and thankfulness for their fortitude grow daily. The fact remains that there are still two attitudes to be found among us. Those who tend to tell and those who tend not to tell. I feel that the tide is turning in favour of telling, and that this is the line I take with students whose task will be greater than ours, but I am not suggesting that late in his professional life a doctor should necessarily change his attitude in favour of telling if he has not been wont to do so, for the path is indeed rocky and tortuous and he may falter to the detriment of his patient.

Dr. Ferriar, the old physician (quoted by Munk, 1887) said: "The physician will not torment his patient with unavailing attempts to stimulate the dissolving system, from the idle vanity of prolonging the flutter of the pulse for a few more vibrations; if he cannot alleviate his situation, he will protect his patient against every suffering which has not been attached to it by nature."

## The Present Role of Surgery in Carcinoma of the Breast [*Précis*]

By E. STANLEY LEE, M.S., F.R.C.S.

*London*

THERE are two approaches to this problem: to look at the disease as an entity, and try to evaluate different methods of treatment relative to the whole; or to select a treatment, such as radical mastectomy, and try to identify a group of cases in which this method gives satisfactory results.

In either case, certain well-known difficulties make valid conclusions hard to reach. These difficulties, big enough within a single series, but much greater when different centres or series have to be compared, include the following:

Firstly, the notorious difficulties of precise clinical staging; largely due to the inexactness of clinical observation and description.

Secondly, the slow tempo of the disease, which makes assessment of results a very slow process; and, because techniques, observers and material are continually changing, makes comparison of any group of cases with a previous group—even at the same centre—fallacious.

Thirdly, our incomplete knowledge of the natural history of the disease; for instance, we do not know if the demonstration of *microscopic* metastases by biopsy invariably means future *clinical* dissemination of the disease.

Even if we could accurately assess the probability of occult general spread in a given case, there would still remain the ethical problem as to how high this probability must be before we abandon "radical" for "symptomatic" treatment.

In the palliative or symptomatic categories, surgery may still play a part in preventing or reducing local symptoms, but each case must be judged individually and surgery is but a small facet of treatment.

In the "curable" categories, the stakes are higher and choice of treatment accordingly more crucial. The choice may lie anywhere between two extremes: minimal surgery designed merely to simplify radiotherapy, and extended radical procedures such as those of Urban or Wangensteen. Experience is, however, tending to show that involvement of mediastinal nodes is indicative of general spread and contra-indicates radical surgery. Pending the emergence of reliable figures, a sensible compromise seems to be to remove surgically what is reasonably accessible, thus enabling the radiotherapist to concentrate his whole effort on the remaining areas. Records show that, where the primary is small and without gross signs of local infiltration, and the axillary involvement is nil or early, local recurrence after radical mastectomy is rare. In these cases, therefore, radiotherapy may be confined to the supraclavicular and internal mammary areas giving them a really satisfactory sterilizing dose in the hope of still further increasing the rate of cure.

# The Comparison of Two Radiotherapy Techniques in Breast Carcinoma [*Abridged*]

By R. W. Gunderson, F.R.C.S., F.F.R.
*Portsmouth*

It has been customary to treat carcinoma of the breast post-operatively, with a tumour dose of 2,000–4,000 r in two to four weeks and this is still widely practised. Since October 1949, the techniques advocated by Baclesse and Lenz using a higher dosage over a longer overall time have been used in Portsmouth.

The first groups of cases were treated prior to this time under the ægis of A. G. C. Taylor of Southampton to whom I am indebted for permission to include them.

An analysis of the very varied dose-time factors used by Baclesse in treating laryngeal carcinoma did not reveal any clear optimum. The mean dose of 5,500 r given in a mean time of eight weeks, modified a little with growing experience, has been used in the second group. The internal mammary chain was also included in this group, whereas in the short course series only the chest wall, axilla and supraclavicular areas were covered.

It is only fair to say that 28 patients who had a genuine simple mastectomy subsequent to October 1949 were included in the short course though only one of these fell into Stage IV. Any bias therefore is in favour of the shorter treatments. Otherwise all patients seen subsequent to October 1949 are included in the ten-week course whether they had radical treatment or not. By general agreement with the surgeons Stage I patients without glandular involvement histologically were not given irradiation and are excluded from the figures presented. Those having recurrent carcinoma when first seen are excluded from both series. Stage I patients are therefore made up of those with glandular involvement on histological examination, and a few patients with growths in the inner quadrants or close to the edge of the breast, where the surgeons concerned felt their prognosis might be helped by irradiation.

## Staging

Manchester Staging has been used throughout. As Stage I were treated by operation only, these had to be a little more strictly defined, otherwise a 70–85% five-year survival could not be expected. Tumours tethered to pectoralis major were relegated to Stage III as were those which were large in relation to the size of the breast. Haagensen and Stout (1951) have shown that the prognosis in larger tumours is a good deal worse, and put the upper limit for Stage I at 6 cm., while Ducuing, Tailhefer, and Baclesse (1948) put it as low as 3 cm. McWhirter, with less strict criteria, has a 60% five-year survival in the Stage quoted for him.

The distribution by stage in each group is a little different, there being only 16% of Stage I cases in the long course as opposed to 27% in the short. Patients not receiving radical therapy constituted 27% of the short course but only 16% of the long. The main reason for this lies in those judged too ill or too old. Failure to complete treatment and the presence of distant metastases affect each group identically.

As the surgeons became more familiar with the relatively mild reactions, pre-operative irradiation was tried in some late cases. A photograph of a patient in Stage III who had a radical mastectomy six weeks after her radiotherapy and a Thiersch graft with a 100% take, was shown. This illustrated the healthy state of the tumour bed and that natural repair and resistance were unimpaired. 6 out of 15 such patients are alive and free of disease at the end of five years, which though encouraging, is of no statistical value.

## Histology

This is available for all living patients. 8 survivals in one group and 6 in the other have been excluded, as histology was not available. Analysis of the type of surgery performed in combination with irradiation showed that 79% in the short course and 71% in the long course had some form of surgery and half those operated on in the short course had a simple mastectomy only, while just under a quarter in the long course had a simple mastectomy with removal of involved lymph nodes. Radical mastectomies were performed on the remainder. 21% in the short course and 29% in the long had no surgery.

Table I shows the overall survival in each group and at each stage. The improvement in results in the long course is suggestive but not statistically significant. It would appear more beneficial to the more advanced cases where surgery alone achieves so much less.

From the patient's point of view the best result is not just survival, but to undergo the initial treatment and to remain free of symptoms and signs, therefore not requiring any

further therapy. Those in the column labelled "recurrence free" satisfy these criteria. No patient received prophylactic ovarian ablation.

TABLE I.—THE FIVE-YEAR SURVIVAL AND RECURRENCE-FREE RATES

| Stage | Short course: No. of patients | Short course: % alive five years | Short course: % free of recurrence | Long course: No. of patients | Long course: % alive five years | Long course: % free of recurrence |
|---|---|---|---|---|---|---|
| I .. | 46 | 57 | 55 | 25 | 60 | 60 |
| II .. | 41 | 37 | 32 | 36 | 44 | 39 |
| III .. | 27 | 19 | 11 | 29 | 38 | 38 |
| IV .. | 48 | 4 | 0 | 68 | 19 | 14 |
| All .. | 162 | 30% | 25% | 158 | 35% | 32% |

The five-year recurrence-free rate in the long course is very close to the survival rate. McWhirter is quoted (Smithers *et al.*, 1952) as having 42·9% alive and only 31·7% recurrence free.

The three-year recurrence-free rates were compared with five-year survivals and found to give 4–8% too optimistic an estimate, though this shorter term criterion might be useful in comparative studies.

TABLE II.—SHOWS THE LOCAL RECURRENCE RATES IN THE TREATED AREA IN STAGES I–III IN THE SHORT AND LONG COURSES OF RADIOTHERAPY

| Stage | Short course: % local recurrence | Long course: % local recurrence |
|---|---|---|
| I .. .. .. | 17% | 8% |
| II .. .. .. | 22% | 17% |
| III .. .. .. | 45% | 14% |
| Total | 25% of 114 | 13% of 90 |

Table II shows the recurrence rates in the treated area: skin, axillary, supraclavicular and parasternal sites are all included. Haagensen with very strict criteria of operability gives 12·5% in the axilla and chest wall only. White (1946) at the Roosevelt Hospital gives 22·6%. Baclesse and Tailhefer (Ducuing *et al.*, 1948) quote 2% for a very strictly defined Stage I, 6% for Stage II and 30% for Stage III with surgery alone. Irradiation only succeeded in improving the Stage III rate to 12%, though their Stage III unlike the Manchester one included those with involved nodes above the clavicle.

Finally I should like to offer some evidence that treatment is worth while and that the repetition of the 39-month average survival deserves less publicity than it has received.

Statistics must be used with discretion and freak occurrences must not bias them unduly. Likewise the length of history is too unreliable to be included. None of the untreated tumours was confirmed histologically when first seen.

TABLE III.—SHOWS THE MEDIAN SURVIVAL TIME BY GROUP AND STAGE
(No. of patients in brackets)

| Stage | Short course | Long course |
|---|---|---|
| I | >5 years (48) | >5 years (25) |
| II | 4 years (44) | 4·5 years (36) |
| III | 2 years (29) | 3·5 years (29) |
| IV | 1·4 years (53) | 1·7 years (99) |

Table III shows the half-life of each group of patients by stage of the disease. It is the median survival time or the time taken for 50% to die. From figures quoted by Daland (1927) on 100 consecutive cases 1·4–1·65 years may be quoted for comparison. The median survival for all cases is two and a half and three years respectively.

To summarize:

The ten-week course gives a more flexible method of treatment and may be used either before or after operation.

It produces a significantly lower local recurrence rate.

The five-year survival rates especially the recurrence-free rates are equal to the best published, when the omission of the bulk of Stage I cases is taken into account.

The local recurrence rate, the most precise measure of the effectiveness of radiotherapy, is markedly diminished by extending treatment to a high dose over ten weeks.

Treatment undoubtedly affects the course of the disease.

No patient in the untreated series was symptom- and sign-free, nearly one-third of those treated had this additional comfort and some hope at least was given to all.

*Acknowledgement.*—I would like to thank the surgeons in the group, especially

Mr. Bernard Williams and Mr. John Younghusband, for their close collaboration, without which this work would not have been possible.

## The Value of Histology in the Prognosis and Classification of Breast Cancer

By H. J. G. BLOOM, M.D., M.R.C.P., F.F.R.
*London*

THE clinical progress of patients with carcinoma of the breast is so variable that perhaps we should be nearer to solving the problems of treatment if we regarded this disease as being caused, not by a single tumour type, but by a group of tumours with a broad spectrum of malignancy.

The outcome of treatment may be quite different even in patients of similar age, with the same duration of symptoms and with tumours of comparable clinical extent. In addition, identical lines of treatment may give variable results, and equally good results have been obtained by radical and more conservative procedures. It is facts such as these which make the management of operable breast cancer still a subject for debate, even though ninety years have elapsed since the first type of radical mastectomy was introduced by Moore of the Middlesex Hospital (Moore, 1867).

The chief purpose of this paper is to present evidence in support of the view that differing opinions regarding treatment have arisen largely from comparing results in groups of patients not strictly comparable, and to propose a more accurate classification of the disease.

The generally accepted classification of carcinoma of the breast provides a guide only to the obvious extent of the tumour. Early death in what appear to have been favourable cases must indicate the presence of highly malignant occult metastases at the time of treatment. Delayed death in advanced cases points to metastases of low-grade malignancy. The failure to detect subclinical metastases in so-called early cases and the inability to assess the speed with which such metastases are likely to develop, are responsible for many of the discrepancies which result from staging.

Can staging be made more accurate? The fallacy of trying to decide whether the axillary lymph nodes are involved or not by clinical examination is well known. About 40% of non-palpable nodes show histological invasion, and some 20% of palpable nodes are histologically free (Harnett, 1948; Haagensen, 1956). The routine microscopic examination of lymph glands from the axilla and also the internal mammary chain (Handley and Thackray, 1954) will, no doubt, add to the value of staging, but even this procedure is open to considerable error. Thus, Saphir and Amromin (1948) find that serial sections demonstrate axillary involvement in one-third of cases previously reported as being histologically free.

Staging, in its present form, will always be of limited value in the study of breast cancer, and it is difficult to see how further improvements in this type of classification can be brought about. Hence, a method of determining the potential malignancy of the tumour may provide a more accurate guide to prognosis than measuring the clinical extent of the growth. By "potential malignancy" is meant the proneness of the tumour to metastasize early or late.

Some indication of the degree of malignancy of breast cancer can be obtained from the histological architecture of the tumour, and it is convenient to express this in terms of a simple numerical grading system. This provides a guide to the likelihood of involvement of those structures not adequately considered by staging, and also to the speed with which metastases may develop, give rise to symptoms and finally cause death (Bloom and Richardson, 1957). Grading of carcinoma of the breast was introduced into this country by Patey and Scarff (1928) who followed the principles formulated by Greenough (1925) in the United States. The method, which is simple to apply and has proved an effective guide to prognosis, is based on three histological criteria, namely, degree of tubule formation, regularity of nuclei, and frequency of hyperchromatic and mitotic figures (Bloom, 1950). Taking the histological picture as a whole each tumour is then classified as being of low, intermediate or high malignancy, grades I, II and III respectively (Figs. 1–3). Needless to say, these three types of tumour are not entities, but merely represent arbitrary subdivisions of a continuous malignant scale. Details and problems of this technique of grading have been described fully elsewhere (Bloom and Richardson, 1957).

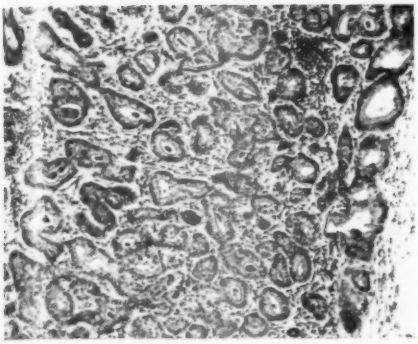

FIG. 1.

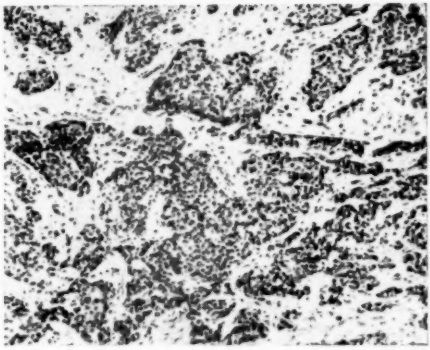

FIG. 2.

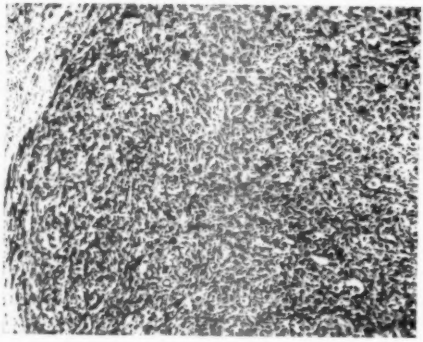

FIG. 3.

FIG. 1.—Highly-differentiated grade I tumour showing well-marked tubule formation, uniform nuclei, and very infrequent mitoses. ×55.

FIG. 2.—Grade II tumour with only very occasional tubules, a moderate degree of nuclear irregularity, and a fair number of hyperchromatic and mitotic figures. ×70.

FIG. 3.—Gross disorder in this grade III carcinoma. No attempt at tubule formation, marked irregularity of nuclei, and numerous hyperchromatic and mitotic figures. ×54.

For further examples *see* Bloom and Richardson (1957).

## MATERIAL

The histological sections of 1,409 female breast cancers, seen at the Middlesex Hospital between 1936 and 1949, have been graded on the lines just described. Approximately one-third of the cases were graded by myself, and the remaining two-thirds in association with Mr. W. W. Richardson. Rather less than half the cases (45%) were found to be of intermediate malignancy; the remaining cases were divided approximately equally between the high and low grades, 26% and 29% respectively.

Only when grading had been completed were the clinical notes examined. It must be pointed out that the figures which follow are based on a selected series of cases because of the necessity of having to have histological material for grading. Although the method of treatment was not uniform, the majority of patients (84%) had a radical or modified radical mastectomy with or without ancillary irradiation.

## GRADE AND PROGNOSIS

The survival rate at five, ten and fifteen years after treatment was determined for each of the three grades of malignancy, and the results are shown in Table I and Fig. 4. A correlation

TABLE I.—HISTOLOGICAL GRADE AND PROGNOSIS

| | 5-year results | | 10-year results | | 15-year results | |
|---|---|---|---|---|---|---|
| Grade | Cases 1936–49 | Survivals | Cases 1936–45 | Survivals | Cases 1936–40 | Survivals |
| I .. | 362 | 75% | 215 | 53% | 96 | 31% |
| II .. | 640 | 47% | 349 | 27% | 162 | 18% |
| III .. | 407 | 32% | 250 | 19% | 101 | 10% |
| Total | 1,409 | 50% | 814 | 31% | 359 | 19% |

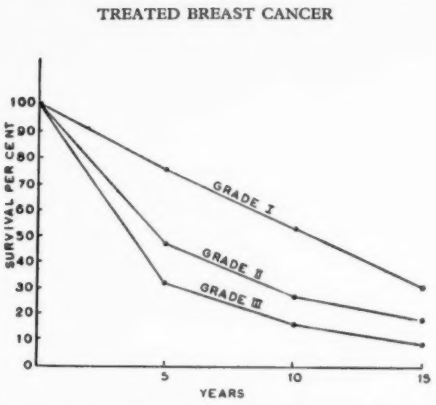

FIG. 4.—Grade and prognosis (5, 10 and 15-year survival rates).

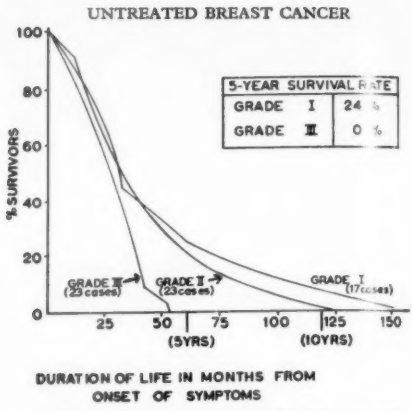

FIG. 5.—Grade and prognosis 63 cases with histology observed at the Middlesex Hospital.

Figs. 4 and 5 are taken from Bloom and Richardson (1957) by kind permission of the Editor of the *British Journal of Cancer*.

has been found between histological structure and prognosis, the survival rate for patients with grade I tumours being two to three times greater than that for grade III cases. The prognosis for grade I cases at fifteen years is comparable with that for grade III cases at five years. It is evident that the survival rate for grade I cases, so promising at five years, eventually proves disappointing in that a steady decline continues throughout the fifteen years of observation. On the other hand, the grade III survival curve shows that most of the deaths from this type of tumour occur within the first five years. Thus, an interval of five years is of considerably less value in determining the results of treatment for women with grade I tumours than with grade III lesions.

### GRADING OF UNTREATED BREAST CANCER

Further support for the concept of three grades of malignancy comes from a study of patients with untreated breast cancer at present being carried out at the Middlesex Hospital. The patients, who were seen between 1805 and 1920, included 63 from whom biopsies had been taken. These have been classified according to grade, and the survival rate, based on the duration of life from *onset of symptoms*, is shown for the three types of tumour in Fig. 5. A clear distinction is again demonstrated between grade I and grade III tumours.

### GRADING OR STAGING AS A CLASSIFICATION FOR BREAST CANCER

Although histological grading provides a useful guide to prognosis it is of no greater value than clinical staging. Both systems of grouping give comparable results (Table II). Adequate information for assessing the stage was not available in 18 cases. The

TABLE II.—COMPARISON OF STAGING AND GRADING FOR PROGNOSIS

| | Five-year survivals | | |
|---|---|---|---|
| Stage | Cases | Grade | Cases |
| 1 | 75% | I | 75% |
| 2 | 43% | II | 47% |
| 3 | 34% | III | 32% |
| 4 | 8% | | |
| Total (1,391) | 50% | Total (1,391) | 50% |

Manchester system of staging (Paterson, 1948) has been used here, but for accuracy, where possible, axillary node involvement was based upon histological examination. Even this method gives practically no more information regarding prognosis than study of a section of the patient's tumour.

### GRADING AND STAGING COMBINED FOR CLASSIFICATION OF BREAST CANCER

Earlier reports have indicated that a more accurate guide to prognosis can be obtained by linking clinical stage and histological grade than by either factor alone (Bloom, 1950*a*, 195 ). This combined classification takes into account both the apparent extent of the tumour when

the patient is first seen and its potential malignancy. The latter provides some indication as to the likely existence and malignancy of occult metastases. The effect of grouping the present series of cases according to stage and grade for prognosis at five, ten and fifteen years after treatment is shown in Table III.

TABLE III.—STAGE, GRADE AND PROGNOSIS

| Stage | Grade | Five-year results Cases 1936–49 | Five-year results Survivals | Ten-year results Cases 1936–45 | Ten-year results Survivals | Fifteen-year results Cases 1936–40 | Fifteen-year results Survivals |
|---|---|---|---|---|---|---|---|
| 1 | I | 162 | 86% | 98 | 55% | 45 | 40% |
| | II | 212 | 70% | 109 | 49% | 50 | 34% |
| | III | 93 | 70% | 58 | 48% | 22 | 27% |
| 2 | I | 120 | 71% | 66 | 58% | 21 | 19% |
| | II | 247 | 42% | 131 | 22% | 50 | 16% |
| | III | 181 | 25% | 103 | 12% | 38 | 10% |
| 3 | I | 63 | 67% | 45 | 42% | 28 | 28% |
| | II | 130 | 30% | 76 | 13% | 41 | 7% |
| | III | 97 | 19% | 64 | 9% | 26 | 0% |
| 4 | I | 11 | 36% | 2 | 50% | — | — |
| | II | 42 | 5% | 28 | 4% | 19 | 5% |
| | III | 33 | 3% | 24 | 4% | 15 | 0% |
| | Total | 1,391 | 50% | 804 | 31% | 355 | 17% |

The number of patients alive at five years ranges from as high as 86% for stage 1, grade I cases, down to a mere 3% for those in stage 4, grade III (Table III). Note the variation in prognosis within each stage where there is, generally speaking, a marked deterioration in survival rate with rise in histological malignancy. The high survival rate of the grade I cases in every stage of the disease is striking. Thus the outlook for grade I cases in stage 3 is more favourable than that for the majority of patients in stage 2 (i.e. those in grades II and III), and almost as good as that for many in stage 1 (i.e. again those in grades II and III). The prognosis for grade III cases in stage 1 appears to be relatively good, indicating that at least some highly malignant tumours are probably still localised to the breast region at the time of treatment. However, these cases constitute only 7% of the total series and 20% of stage 1 patients.

The ten-year follow-up of some 800 patients reveals a comparable pattern of results with 55% survivals at one end of the scale and 4% at the other end. The same pattern is again seen in 355 patients who have been followed for fifteen years and the corresponding figures are 40% and 0%.

This clinico-pathological classification reveals that hope need not be abandoned even for patients with stage 3 breast cancer, provided that their tumours are of low-grade malignancy. Furthermore, it seeks to explain some of the disasters among stage 1 patients and many of the disappointments in stage 2, the failures in either stage being largely due to the presence of the more malignant grade II and grade III tumours.

## FACTORS WHICH MAY INFLUENCE THE GRADE OF MALIGNANCY IN BREAST CANCER

Nothing is known of possible hereditary, racial or geographical factors upon the incidence of the three grades of malignancy. The patient's age, so often claimed to be of importance in prognosis, has been found without influence on tumour type (Bloom, 1950*b*). At the present time the only known factor capable of influencing the grade of breast cancer is child-bearing.

Carcinoma of the breast, when associated with pregnancy or lactation, carries a particularly bad prognosis (White, 1955). In my series of 90 patients (Bloom, 1955) the majority of the tumours (64%) were of high malignancy (grade III), whereas only 4% were classified as grade I. This is in marked contrast to the general series reported here where there is approximately an equal incidence of low and high grade tumours, 26% and 29% respectively.

## CONCLUSIONS

The relative value of different lines of treatment in breast cancer appears impossible to assess accurately, whilst patients with tumours of widely differing malignancy continue to be grouped together for comparative studies. Such heterogenous groups of cases are produced by clinical staging and the widespread use of this system may be responsible for at least some of the confusion concerning treatment. The position is unlikely to be clarified

until a more accurate classification of the disease is employed. The combination of clinical staging and histological grading is offered as a step in this direction.

I would like to express my gratitude to Professor B. W. Windeyer and Professor R. W. Scarff for facilities to work on the problems associated with breast cancer, and to the many surgeons whose cases have been studied.

## Vision, Photography and Electronics in Radiology [*Précis*]

By G. E. DONOVAN, M.D., M.Sc., D.P.H.
*Swansea*

and E. STAFFORD, B.Sc., B.A.
*Manchester*

THE study of radiographs involves the light-adapted eye which perceives contrast differences best in the range 10 millilamberts to 10 lamberts. A modern illuminator approximates to 450 millilamberts. Adaptation to light is rapid and is nearly complete in the first half-minute. In contradistinction dark adaptation takes place more slowly and continues for about twenty-four hours when a brightness value of 0·000001 millilambert may be perceived. Increase of sensitivity rises steeply for the first twenty minutes.

Dark-adapted vision is mainly by rods which means that there is a relative central scotoma. This is important in fluoroscopy.

Since rods are poorly sensitive to red light the wearing of red goggles for dark adaptation has a physiological rationale.

Dark adaptation becomes less effective with age, the light perception being about twice as good at 20 years of age as at 40, after a given period of dark adaptation.

The visual acuity (i.e. resolution of fine detail) falls with low intensity of light. Where in a good light points 0·0006 in. apart can be resolved into two, this may increase to 0·04 in. under conditions of fluoroscopy. Similarly intensity discrimination which may allow a 1% difference to be perceived in daylight may be as low as 40% in screening a thick subject.

Dr. Donovan dealt with factors which facilitate *good interpretation* of the radiograph which involves an interplay of experience and intelligence on the part of the observer with an optimal presentation of the data in the film.

Factors related to *definition and contrast* in the negative were discussed.

Some aspects of *density differentiation* and the possible application of colour to the recording of different tissue densities were mentioned.

*Image intensification.* Various devices either now in use or potential methods of intensification were briefly discussed with the advantages and defects of the present systems.

Experiments are now going forward with *electro-luminescence* as a source of energy magnification which involves only a thin plate comparable to the present X-ray screen. This has interesting possibilities and may be the eventual answer.

The paper ended with a reference to the influence of *automation* in future development.

## Thudichum and the Medical Chemistry of the 1860s to 1880s

By HENRY MCILWAIN, D.SC.

*Department of Biochemistry, Institute of Psychiatry, Maudsley Hospital, London*

JOHANN LUDWIG WILHELM THUDICHUM (1828–1901) has been claimed as the father of neurochemistry; in this sphere I see him as a notable successor to many previous workers (McIlwain, 1958), and here I wish first to indicate his position in the medical chemistry of the mid-nineteenth century.

Sudhoff (1932; Table I) describes how, when Thudichum was about 18 years old, his

TABLE I.—J. L. W. THUDICHUM 1828–1901: SYNOPSIS OF CAREER AND PUBLICATIONS

| | |
|---|---|
| 1847 | Meets Liebig; enters the University of Giessen. |
| 1851 | M.D.Giessen. Thesis: "Fractures of the upper end of the humerus". |
| 1854 | M.R.C.S.London. |
| 1856 | Physician, St. Pancras Dispensary. |
| 1858–63 | Lecturer in Chemistry, Grosvenor Place School of Medicine. |
| 1858 | A Treatise on the Pathology of the Urine (Churchill, London: 2nd edit., 1877). |
| 1863 | A Treatise on Gall-stones (Churchill, London). |
| 1865 | Lecturer in Pathological Chemistry, St. Thomas' Hospital. |
| 1866–82 | Research for the Medical Officer to the Privy Council and later to the Local Government Board, appearing in the Public Health Reports. |
| 1872 | A Manual of Chemical Physiology including its points of contact with pathology (Longmans, Green, Reader & Dyer, London). |
| 1872 | A Treatise on the Origin, Nature and Varieties of Wine (with A. Dupré. Macmillan, London). |
| 1879–81 | *Annals of Chemical Medicine, including the application of chemistry to physiology, pathology, therapeutics, pharmacy, toxicology and hygiene* (Longmans, Green, London). |
| 1884 | A Treatise on the Chemical Constitution of the Brain (Baillière, Tindall & Cox, London). |
| 1886 | Anatomischen und Klinischen Chemie (Berlin). |
| 1894 | A Treatise on Wines. Their Origin, Nature and Varieties, with Practical Directions for Viticulture and Vinification (Bell, London). |
| 1895 | The Spirit of Cookery (Baillière, Tindall & Cox, London). |
| 1901 | Die chemische Konstitution des Gehirns des Menschen und der Tiere (Pietzcker, Tübingen). |

father consulted Justus Liebig about the analysis of mineral waters from a newly discovered spring. The son Ludwig met the great chemist and was oriented towards chemistry before he entered the University of Giessen as a medical student. Here he obtained his doctorate in 1851 with a thesis on an anatomical subject; but even before this he had worked with Liebig in the inspiring environment of his busy and pioneering laboratory; he regarded himself throughout his life as Liebig's pupil. His position in Giessen (in Hesse) was, however, made difficult because a few years earlier during war with Denmark he had served voluntarily in a medical capacity in the army of Schleswig-Holstein. In this situation he left for London where a family he already knew well had recently established themselves: in particular Augustus Dupré who had become Lecturer in Chemistry at Westminster Hospital Medical School, and his sister Charlotte who married Thudichum soon after he arrived in London. Thudichum also promptly obtained his M.R.C.S.; then an appointment as physician, and he was in medical practice throughout his life, especially as an otologist and rhinologist. He contributed papers in this specialty, and devised a "Thudichum nasal speculum" but these activities form a small part only of his scientific output.

Thudichum's chemical interests first found official expression in England in 1858 through his appointment as lecturer in Chemistry at the Grosvenor Place School of Medicine. Later he was lecturer in pathological chemistry at St. Thomas's Hospital, and director there of the newly founded pathological and chemical laboratory (Obituary, 1901). He was thus concerned just a hundred years ago, with teaching to medical students the rapidly expanding subject of medical chemistry. In 1858 he published his first book, on the analysis of urine.

Teaching and writing in medical chemistry underwent a considerable change in the second quarter of the nineteenth century: during, that is, the period between Thudichum's birth and his beginning as a lecturer. At the beginning of the 1800s, chemistry was being taught to students of medicine in some if not all the medical schools in Britain, but taught in much

the same fashion as chemistry would be taught to students in science. Paris's (1825) "Medical Chemistry" is an example. Though addressed very specifically to students of medicine, the book has throughout an entirely chemical framework and a large part concerns purely inorganic chemistry. Much of the material taught was in fact that of our present school chemistry (and physics) which of course is still taught with a purely chemical logic, as a means of introducing chemical principles and discovery, whether or not the students concerned are later to be trained in medicine or another subject.

It can thus be seen that the type of medical chemistry on which Thudichum began to publish in 1858 was a relatively new subject: representing a stage in the formation of what became the typical physiological chemistry as it was taught in medical schools in the decades around 1900. I would like therefore to look more closely at the environment in which this first book appeared.

Firstly, Thudichum's was one of several books on the same general subject published in the middle of the last century. In the decade 1854–1865, the Surgeon-General's Catalogues and other sources indicate the books of Table II, concerning analysis of urine, to have appeared together with about an equal number of publications in thesis or analogous form.

TABLE II.—THUDICHUM'S FIRST BOOK WITH COGNATE PUBLICATIONS

Neubauer, C. (1854) Anleitung zur qualitativen und quantitativen Analyse des Harns. Wiesbaden.

Hellerman, J. F. (1855) Pathological Chemistry of the Urine. Trans. L. Dahl. Dublin.

Beale, L. S. (1856) Tables for the chemical and microscopical examination of urine in health and disease. London.

Thudichum, J. L. W. (1858) A Treatise on the Pathology of the Urine, including a complete guide to its analysis. London.

Parkes, E. A. (1860) The composition of the Urine in health and disease and under the action of remedies. London.

Beale, L. S. (1861) On Urine, Urinary deposits and calculi, their microscopic and chemical examination. London.

Hassall, A. H. (1863) The Urine in health and disease, being an exposition of the composition of the urine and of the pathology and treatment of urinary and renal disorders. London (1st Edition, 1859).

Neubauer, C. and Vogel, J. (1863) A Guide to the qualitative and quantitative Analysis of the Urine, designed especially for the use of medical men. Transl. Markham, New Sydenham Society, London.

All these were practical handbooks dealing with this relatively narrow subject, and before and after this especially prolific decade such publications were less frequent. Thudichum's deals with urinary constituents and does not, for instance, begin with a general statement of kidney function or the role of the urine or its relationship to the blood. Although these subjects are touched on in dealing with individual constituents, they form a very small and disconnected part of the whole, as also do the book's pathological aspects.

Now both before and since the 1850s, many more general books on physiological chemistry appeared. An example, very relevant to Thudichum in London, was the "Practical Handbook of Medical Chemistry" of J. E. Bowman of King's College, London, which went through three editions between 1850 and 1855; designed as a "small manual giving instruction for the examination and analysis of urine, blood, and a few other of the more important animal products, healthy and morbid; and comprising also, directions for the detection of poisons in inorganic mixtures and in the tissues". Nearly half of this book deals with urine, but from a practical point of view it is very different from its successors of Table II. The methods both for urine and blood in Bowman's book are very cumbersome, depending largely on actually separating and weighing constituents, including urea. An analysis begins with 10 or 12 oz. of blood.

By contrast, the manuals of what we may call the new analytical specialists of Table II were excellently businesslike. Several volumetric methods are described, which are much more speedy than gravimetric ones. Thudichum with the other authors was, in effect, presenting some fifty years' research by many investigators on the application of analytical methods to bodily materials, with the object of aiding diagnosis and treatment. To appreciate this, it may be noted, firstly, that Fourcroy at the end of the eighteenth century began the section on the animal kingdom in his "Elements of Natural History and Chemistry" (1790) by saying how the analysis of animal substances in general was in a much more imperfect state than other branches of the science. With respect to urine, he writes "The state of the stomach, and particular humours . . . cause infinite diversity of changes in this fluid, to ascertain and estimate which, a long series of experiments would be requisite, which have, as yet, only been pointed out as necessary."

Secondly, if we look at the achievements of the years before the publications of Table I, we find they had been unusually prolific, and feature many subjects and names still familiar in physiological chemistry. Thus, though the volume and sweetness of the urine had long

been prominent in diabetes mellitus, Trommer first developed a chemical test for the sugar, depending on oxidation by alkaline copper salts, in 1841; Fehling's quantitative method came only in 1850. The peculiar smell of the breath in this condition was definitely ascribed to acetone, and a test for this in urine devised by Petters in 1857. Albumin was noted as an abnormal constituent of urine in 1812, and the biuret test for urinary albumin described in 1833; Millon's reaction for proteins dates from 1849. In 1848 Bence-Jones reported the urinary proteins associated with a particular softening of the bones. Pettenkofer's test for bile-salts in urine came in 1844.

Chemical analysis was thus making real contributions to the understanding and diagnosis of disease and this new, applied medical chemistry largely concerned the urine. The nature of the urine makes it understandable that it, rather than other body fluids or tissues, should first have received the large attention indicated by Table II. It contains relatively little of the proteins, mucilages and formed elements which make blood, milk or flesh more difficult to examine. Simple substances such as urea and inorganic salts form a large part of its solid matter. Apart from the examination of the urine to aid the diagnosis or treatment of disease, two other stimuli to its study can be recognized in the first half of the 1800s, perhaps especially in Thudichum's work. First, the examination represented part of the growing organic chemistry of the times: a wide variety of materials associated with living organisms were being ransacked for their chemical constituents, which were being analysed and the analyses collated to yield chemical patterns. These had not in Thudichum's book of 1858 become the structural or even empirical formulæ of to-day: the subject was in his time still in course of development. Secondly, the analyses of foodstuffs, tissues and excreta were giving real enlightenment in physiology and here Liebig, with the new concept of metabolism expressed chemically, was a pioneer.

The books of Table II, which reflect this first major application of chemical analysis in medicine, appear from this distance to represent the type of technical elaboration through which a new specialty frequently passes before taking its place as a valuable but limited tool, available with the minimum of trouble to those who are to apply it to practical problems. Of all the books, Thudichum's probably represents the greatest chemical elaboration. Its organisation is purely chemical, with some 50 chapters, mostly of a few pages and dealing with an individual urinary constituent or group of constituents. These chapters are usually excellent, brief, well-documented monographs on the constituents concerned, giving, for instance, their chemical nature, discovery, chemical and physical properties, isolation or determination. But often less than half of the account deals with the substance as it occurs in urine. Thus there are described the crystallography of sodium chloride, the solubility of creatine, the chemical synthesis of urea: information for which one would now consult texts on inorganic chemistry, physics, or organic chemistry. On the other hand, it is to be emphasized that knowing as much as possible about the chemistry of all urinary constituents did give the basis for the discovery of new constituents and for the development of new analytical methods. Thus Thudichum's book might have been a manual for those who were hoping to make new chemical discovery regarding the urine in pathological conditions, though actual achievement in this respect formed only a small part of it.

Thudichum's next major work concerned a second subject which was typical of the growing chemical pathology of the time: "A Treatise on Gall Stones: their Chemistry, Pathology and Treatment" (1863). It has fewer compeers than his book on urine; in his Introduction Thudichum states his aim of giving an account of the chemistry of gall stones comparable to Morgagni's description of their physical nature. The book displays Thudichum not only as a chemist, but also as a microscopist, for he found casts of bile ducts in the centre of the stones; and as a theorist, for he writes fifty pages on previous chemical work, and in a final section nearly as long he debates both chemical and physical factors in the formation of the stones. Here he emphasizes the presence of the bile acids as binding materials and concludes the stones to be formed "by a decomposition of the bile akin to putrefaction". But this is too early a date to expect adequate experiments in such matters; Thudichum's experiments on the changes occurring on standing bile for some years are not impressive. More noteworthy are his isolation of bile pigments from the stones, and his contribution to their chemical classification. Also, two similarities between the investigation of urine and gall stones are worth bearing in mind in relation to Thudichum's subsequent work. First, presumably in his search for chemically tractable materials, Thudichum has chosen to study a very limited part of the body. Second, he is working within a limited range of chemical study, being primarily concerned with the isolation and analysis of chemical substances.

### Thudichum's Practical Work and Work on the Brain

Thudichum's book on the urine, and also his later "Manual of Chemical Physiology" (1872) are eminently practical books: they give excellent manipulative instructions and much quantitative data needed by a laboratory worker. I would now like to indicate the circum-

stances in which the greater part of Thudichum's laboratory work was carried out, for they were unusual in his day and would also be so in ours. Thudichum had received his training under Liebig who from the 1830s was a pioneer in teaching by laboratory investigations, and as such attracted workers from all over Europe and beyond. It is understandable that the facilities which Thudichum first obtained with his hospital or medical school appointment fell far below this standard, though in his second appointment, at St. Thomas's, he was director of a new pathological and chemical laboratory and some work published in 1869 is described as being performed there. The bulk of his work, however, both before and after that time, was carried out in a laboratory which he had established in his private house. More remarkable, Thudichum was given support or expenses from Government sources. This took place through his carrying out investigations for the Medical Officer to the Privy Council initially into the chemical pathology of infectious diseases. Such payment for work done was perhaps not fundamentally different from payments to medical consultants or to consultant analysts. With Thudichum, however, the arrangement was unusual in being primarily for research, in what became quite a broad and abstruse subject, and which lasted for some years. The Medical Officer concerned, whose attention had been attracted by Thudichum's work and who charged him with these investigations (Obituary, 1901; Sudhoff, 1932) was the notable Sir John Simon. Simon was initially responsible to the Privy Council and so in a relationship similar to that of the Medical Research Council established some forty or fifty years later. In the latter part of Thudichum's work Sir John Simon was responsible to the Local Government Board.

At first Thudichum carried out analyses on material on which Simon made other pathological studies but shortly Thudichum's work appears to have become entirely independent. Quite early he had qualified assistants. Throughout, his work appeared in the Annual Report of the Medical Officer, introduced by Simon but often carrying long technical supplements by Thudichum in which he gave theoretical and practical details of his work. Thudichum more than anyone else appears to have availed himself for sixteen years of this opportunity to make the Reports a medium for publishing in what we would now regard as the basic medical sciences. Moreover the Reports at least in one quarter almost became known as a periodical in biological chemistry: Chittenden (1930) in his history of physiological chemistry in the United States describes them as eagerly awaited there. On the other hand, this mode of publication probably contributed to some of Thudichum's work being overlooked. Much of it, however, was published a second time either in ordinary journals or, after a lapse of some years, in book form.

Thudichum's studies for the Medical Officer were clearly planned as a fundamental attack on a major medical problem of the time. He begins his first report: "The object of these researches, proposed to me on the 7th August 1866 by the Medical Officer of the Privy Council were as follows: 'By investigation of choleraic discharges, and of the diseased body after death, and by such auxiliary observations of the sick as may be needful, to ascertain *what successive chemical changes are undergone by the body in the progress of cholera, and what relation subsists between those changes and the symptoms presented by the patient during life*'." Thudichum's previous work clearly fitted him for such studies, and his report on this occasion covers some 50 pages, giving examinations of urine, blood, bile, stools, muscle and liver from many cases; describing new methods in detail including the use of the spectroscope in which Thudichum did pioneer work.[1]

In 1868 and in subsequent years the direct study of cholera has less prominence and Thudichum's section in the Reports is headed *Researches intended to promote an improved chemical identification of diseases*. Thudichum in 1868 argues this subject in general terms, not confining himself to his own researches but writing rather in textbook or monograph style, concluding, for example, that "Ultimate pathology cannot, I think, be cellular, as was claimed by Virchow". He notes that not enough is known of the constituents of bodily organs to make likely the detection of chemical change in pathological conditions. Here he instances the relatively well-investigated extract of muscle (Thudichum had written on Liebig's meat extract), pointing out that in spite of much investigation some five-sixths of its constituent material was still unidentified. This is the light in which we are to see Thudichum's detailed chemical studies: and very detailed they were. For example, the

[1]An interesting sidelight on Thudichum's spectral analysis is described by Duncum (1947). During the 1860s Thudichum demonstrated its abilities to the Medical Society of London and used cylinders of compressed oxygen and hydrogen for his source of light. This was observed by Charles James Fox, who was seeking a way to make nitrous oxide manageable for anæsthesia. Fox persuaded the firm of Coxeter to compress nitrous oxide for anæsthetic use and from 1870 was using it widely in the Dental Hospital, London. At this point we have a reminder of Thudichum as a patriot and humanitarian, for during the Franco-Prussian War he is described as making an urgent newspaper appeal for the supply of nitrous oxide for military surgery. Over £180 was subscribed to a Nitrous Oxide Fund and Coxeter supplied over 5,000 gallons of the gas for this purpose, Thudichum going to the theatre of war to see it applied.

examined urinary pigments, and the pigments of bile and gall stones; reported on "a new series of yellow compounds contained in animals and plants" which Rosenheim (1930) later took as pioneering work in carotenoids. He studied proteins and amino acids, characterizing a new amino acid "glycoleucine", or norleucine.

Moreover, it was in this spirit and background that Thudichum carried out his major original work which was on chemical constituents of the brain. His first large report of his own investigations in this subject came in 1874 and his book, "The Chemical Constitution of the Brain," in 1884. It is clear from both these sources and also from John Simon's own Reports, that Thudichum was carrying out very extensive and purely chemical studies of the normal composition of the brain, usually of ox brain, in order to understand and control the deliria and coma of cholera, typhoid, and other infections. To appraise this we must recall the late 1860s when Thudichum's work on cholera began. Fevers with their prominent, distressing, mental symptoms, were the major medical problem of the day. Bacteriology had not begun. Microscopic observations of the brain were still rudimentary. Presumably it seemed reasonable to others as well as to Thudichum, that chemistry which could demonstrate abnormal glucose or urea in a normal-looking urine, might also help to specify the material basis for disorder in a normal-looking brain. At any rate one can imagine it worth trying. Thudichum, however, had a rather more rigid view and even in 1884 appears to be making little attempt to consider what was the most profitable line of attack. For he was primarily a chemist and had found great chemical complexity in the brain. As he wrote after his twelve years of investigations, "unforeseen complications arose". His list of chemical substances isolated from the brain, and either partly or completely characterized, runs to some 140 (Thudichum, 1901). I have appraised elsewhere something of the great enterprise and some shortcomings of this work (McIlwain, 1955, 1958; Page, 1937). Thudichum's purifications and analyses were very painstaking, and were carried out at a time when about a gram of material was required for adequate characterization and analysis. Much of this work, therefore, may never again be done in the same way or on the same scale; and we are fortunate that some of Thudichum's specimens have been preserved. In 1930 Dr. Rosenheim of the National Institute for Medical Research visited two daughters of Thudichum and was given laboratory records, other writings of Thudichum, and also a large collection of his chemical specimens. These were exhibited to the Biochemical Society in 1930 and are now at the National Institute, Mill Hill.

In the present setting we may note that Thudichum, although knowing how much more difficult would be his new task than that of the chemical understanding of urine or gall stones, nevertheless tackled it energetically. I wish to emphasize that Thudichum still, in 1884, wrote "When the normal composition of the brain shall be known to the uttermost item, then pathology can begin its search for abnormal compounds or derangements of quantities. . . . The knowledge of the composition and the properties of neuroplasm and of its constituents will also aid us in devising modes of medical treatment. . ." Here he was doing little more than restating his programme of twelve years ago, perhaps in the hope that others would continue his work. For he was then 56 years of age, still active in medical practice, with a family of six children and with many other interests. In the report dated December 1883, George Buchanan as Medical Officer wrote "Dr. Thudichum has now completed those profound researches into the chemistry of the brain, on which he has been so long engaged for the Board. . . His researches have shown, he says, the brain to be the most diversified chemical laboratory of the animal body; all other organs being much more simple and very much less specific in their chemical constitution than the organs producing and conducting nerve power". This conveys the enthusiasm of a specialist, with a turn of phrase about nerve power which betrays ignorance of a quarter century of physiological study of the nervous system. The phrase is Thudichum's; it appears in his book of 1884.

### Chemistry in Physiology and Medicine

In 1872 appeared his "Manual of Chemical Physiology including its points of contact with Pathology". Like his book on urine, this is one of a number of books on the same general subject produced by different authors at this time. Thudichum's begins in a familiar fashion with an account of digestion; of the chemical effects of saliva, gastric and pancreatic juices. He naturally has a section on the brain, but the most distinctive part is the relatively large and detailed "analytical guide" giving excellent laboratory descriptions of experiments to display the chemistry of the component tissues and substances of the animal body. Many experiments are of a type which has persisted through the subsequent eighty years, and one may suspect it to be Thudichum's medical school experience which prompted him to write in the book's preface ". . . I think it improbable that ordinary students of medicine will go easily through the whole of its matter in the laboratory. I hope therefore that teachers of chemistry who will make use of the guide will select the reactions and analyses to be performed by each student, according to his knowledge, ability and intentions". Conceivably because of its

good practical guide as well as the date of its publication, this was the first text on physiological chemistry to be used in the United States when, in 1874, the subject began to be taught with laboratory work at Yale (Chittenden, 1930).

Of very different character are the two volumes of Thudichum's *Annals of Chemical Medicine, including the application of chemistry to physiology, pathology, therapeutics, pharmacy, toxicology and hygiene* (1879, 1881). This was intended to be an abstract or review journal in the subjects named. It thus represented a considerable enterprise, and was the nearest approach in English to Maly's *Jahresbericht über die Fortschritte der Thierchemie* which had been published since 1873. In general, Thudichum's like Maly's consisted of annoted summaries of publications from all sources. It also, however, contained much of Thudichum's own work and was nearly all written by himself. Moreover, from time to time it displays Thudichum polemically defending details of his previous work. Thus he felt, probably rightly, that his work had been slighted or distorted by certain authors including Gamgee in this country and Hoppe-Seyler in Germany; here, in the *Annals*, Thudichum forcefully gave his opinions. Less excusably, the *Annals* also occasionally displays really splenetic views of work which Thudichum was not in a good position to judge. One treated so was Kühne on his discovery of the bleaching of visual pigments by light, observations which Thudichum disparaged and mocked (*see* McIlwain, 1958). For Thudichum was a protagonist not of all types of application of chemistry in medicine, but of one particular type: the separation, purification, and analysis of compounds from natural sources.

Thudichum must have realized a growing lack of sympathy with this aspect of his work and outlook. Only two volumes of the *Annals* were published. He had been a Vice-President of the Chemical Society, but at the Physiological Society was involved in polemical discussions. In these one may suspect Thudichum to have been right in chemical detail but narrow in outlook. In spite of his work, incidents such as these and such as his criticism of Kühne were a disservice to the furtherance of chemistry in physiology and medicine. They may contribute to explaining how Thudichum had no immediate successors. He was further isolated in that his medical practice was in a quite different specialty from that in which he did his major research. At least three of four people had collaborated in his work, but he appears to have had little opportunity for establishing a teaching laboratory, or perhaps by choice to have put his energies elsewhere. A wider, university atmosphere might have corrected his dogmatic and polemical tendencies.

In these circumstances it is understandable that Thudichum developed others of his many interests. Since the 1870s he had been concerned with the analysis of wines, making reports to the Pure Wine Association, London. A paper in 1870 has the intriguing title "On wines, origin, nature, analysis and uses; with special reference to a new alcoholic drink made from tea". In the 1890s, his development of this theme is seen by his books on food and wine (Table II). He also continued in medical practice. When in 1901 he published a German version of his book on the chemistry of the brain, there was little to add to his work of twenty years before. In one sense this is a measure of the magnitude of Thudichum's contributions; in this field he had worked assiduously even though he did not supersede the techniques of his predecessors. Here we come to a general point in the development of the sciences. In one sense biochemistry developed from the organic chemistry of the time of Liebig. In another sense it represented a sharp break, a refreshing and inspiring new way of approaching chemical problems in living organisms. There are few better demonstrations of this than the life of Thudichum.

I am greatly indebted for assistance given me at the Libraries of the Royal College of Surgeons, the Wellcome Foundation, and the National Institute for Medical Research.

## BOOK REVIEWS

**Anatomy for Nurses.** By D. V. Davies. (Pp. ix + 371; illustrated; 20s.) London: The English Universities Press. 1957.

As noted in the preface, "This volume is intended for nurses . . . to cover the syllabus in anatomy as set out by the General Nursing Council for the Preliminary State Examination". The work achieves its purpose, and the nurse who has digested its contents will have a good working knowledge of the anatomy of the human body. The author writes simply and clearly and has succeeded in avoiding much inappropriate detail. More still might, however, have been omitted with benefit, e.g. the foramina of the base of the skull, the complete list of names of the carpal and tarsal bones, the detailed classification of joints, and some of the details of intracerebral anatomy. In certain sections, the anatomy is made clearer by a discussion of function, the best example being the reproductive system. Perhaps the author is seeking to stimulate the authorities responsible for the education of nurses into considering the whole of anatomy on a functional basis, and merging it with physiology into a common subject. If so, most educationists will wish him good luck with his efforts. But like all who try to write sound but simple textbooks for nurses, the author will have to breach the Maginot Line constituted by Sister-Tutors and fortified by tradition.

**Fluid Balance Handbook for Practitioners.** By William D. Snively, Jr., M.D., A.A.G.P., and Michael J. Sweeney, M.D., A.A.P. (Pp. xix + 326; illustrated. 51s.) Oxford: Blackwell Scientific Publications, 1956.

The problem of "Fluid Balance" cuts across many established boundaries between medicine and surgery and its proper management requires considerable knowledge of basic physiological facts as well as clinical judgment. A simple handbook on this subject would unquestionably be of great interest and value. It is, however, a notoriously difficult subject to present to the uninitiated and an even more difficult problem to try at the same time to clarify and consolidate the information of those who have made a special study of some medical or surgical aspect.

The general plan of this book is excellent. It proceeds from Foundation Facts to Clinical Diagnosis and then to Therapy including practical details of administration and finally illustrates the whole theme by analysis of clinical cases. It is a gold mine of factual information, but unfortunately, the reader must be prepared to sift this gold from a large dross of irrelevance and repetition. Similarly the language which may be suitable for contemporary transatlantic readers is strangely incongruous to us. For instance, "A century and a half ago, a strange German religious sect, the Rappites, founded the community of Harmonie on the banks of the Wabash. They built well and their sturdy, ivy-covered brick buildings still stand. Their leader was George Rapp, and therein lies our tale, for the name RAPP spells out the first letters of the end organs which provide automatic normalization or homeostasis of the fluid volume, electrolyte concentration and electrolyte composition of the body fluids. These homeostatic controls include the Renal, Adrenal, Pituitary and Parathyroid mechanisms. They are key units of a fantastically complicated regulatory system which puts man-made automation to shame". Again the effort to maintain simplicity not only makes several of the diagrams unnecessarily elaborate, but results in this sort of statement "If the pathologic state results in an increase of carbonic acid, a carbonic acid excess results." Again the figure to illustrate the clinical picture of Calcium Deficit has on it under a heading "Clinical History" a list of sixteen clinical diagnoses with no further indication as to how these conditions could bring about calcium deficiency. This endeavour to make each figure all inclusive defeats its own object of simplicity. It may, of course, be useful as a reference book for someone faced with an unfamiliar problem. No doubt the authors armed with a fluid imbalance analysis sheet (Table 8), laboratory values useful in diagnosis (Table 1, Chapter 14) and the daily fluid balance sheet (Table 2, Chapter 14) are in an excellent position to deal with problems requiring an urgent solution. Indeed the final analysis of clinical cases in Part 7 would seem to substantiate this claim. However, there are few in this country who will have the patience to assimilate facts presented in this manner.

**Recent Outbreaks of Infectious Diseases.** By S. Leff, M.D., D.P.H. (Pp. xii + 408. £1 15s.) London: H. K. Lewis & Co. Ltd. 1957.

Dr. Leff has followed the example of Greenwood in directing this book on epidemics not only to medical men but also to other health workers and to the public. In his classic work on "Epidemics and Crowd Diseases" Greenwood argued that the discussion on things assumed to have happened did happen needs logic and common sense, of which the

medical profession has no monopoly. Epidemiology perhaps alone among the medical sciences requires little clinical or technical knowledge to be understood. This is fortunate as the control of epidemic disease depends increasingly upon the intelligent co-operation of laymen, for whom there are few appropriate written sources of information. In his choice of outbreaks and most readable accounts of them, the author demonstrates that his subject can be fascinating for readers with or without medical training.

The change that is taking place in the relative importance of virus and bacterial disease is reflected in the fact that rather more than half the book is devoted to smallpox, poliomyelitis, Q fever, psittacosis and Bornholm disease. The smallpox outbreaks are particularly well described and lead to an excellent summary of lessons learned, but the two outbreaks of poliomyelitis selected might be considered atypical and the conclusions unjustified. Outbreaks of enteric fever and food poisoning occupy a further large section, to which one due to *Cl. welchii* would be a useful addition. The remainder of the book deals briefly with diphtheria, and, somewhat surprisingly, lead poisoning and atmospheric pollution. One would be happy to see a slight alteration in the title and the inclusion of further outbreaks of non-infectious disease as interesting as that of lead poisoning in Rotherham.

A useful service has been performed in bringing together many notable epidemics. The descriptions are lively and readable, and are followed by some excellent comments, particularly on practical and administrative aspects. In some sections, unfortunately, the epidemics occupy a secondary rather than primary place, being reduced to the rôle of illustrations of an epidemiological argument. The preliminary remarks on the clinical, and bacteriological features of some of the diseases are unduly long and include unnecessary technicalities. It is probably impossible for one volume to be both textbook and collection of detective stories, and the main defects of this book result from failure of the author to keep a weakness toward textbook writing in check. It is nevertheless well worth reading.

**The Clinical Application of Antibiotics.** By M. E. Florey, M.D. Volume III Chloramphenicol and the Tetracyclines. (Pp. ix + 393; illustrated. 84s. 0d.) London: Oxford University Press. 1957.

The purpose of this book is to evaluate critically the data on which the present use of antibiotics is founded. Four antibiotics are covered: chloramphenicol and the three members of the tetracycline group—chlortetracycline (aureomycin), oxytetracycline (terramycin) and tetracycline itself. Each antibiotic is dealt with under three main headings. The first chapter for each gives general considerations, then the range of antibacterial action, the complications of therapy, the main results of clinical trials and methods of administration. The second chapter deals with treatment of diseases due to specific organisms and the third with the treatment of diseases considered by systems, age groups or sex. There is an additional very short chapter on the effect of chlortetracycline on growth, thus making 13 chapters in all.

In discussing a book packed so full of important facts, it is only possible to select a few features for special comment. Under each antibiotic tables are given showing the antibacterial activity as judged by *in vitro* sensitivity tests on as wide a sample of organisms as possible. An important section in the part devoted to chloramphenicol is the discussion of the blood changes which have been attributed to the drug. The evidence for its toxicity is well and fairly presented and sensible conclusions are drawn about its use. The treatment of the tetracyclines was clearly a difficult problem to which the author has devoted a good deal of thought. It must have been difficult to decide whether to deal with the various aspects of the clinical use of all three antibiotics together or, as the author has done, to treat each of them separately. Either method has disadvantages. The method adopted, though perfectly clear in a purely factual sense, leaves the reader with a bewildered feeling that there is very little to choose between the three tetracyclines and that what is said about one of them could be said about another. This of course is broadly true and is, in fact, explicitly stated in the Conclusion on p. 335. But it is also pointed out on the same page that there are a few specific differences between the three tetracyclines. Yet there is no critical account of the possible importance of these differences nor of the indications which might in special cases justify the use of one tetracycline rather than another. This would have been achieved more easily if, under the heading of each disease or system, all three antibiotics had been dealt with one after the other and then compared.

The book is well produced and there are useful tables, graphs and plates illustrating important features—for example, temperature charts or photographs showing the response of patients to treatment. It is unfortunate in a book of this quality that there are many errors in the references. These are noted in a special list at the beginning of the extensive bibliography. The book gives a full account of the state of our knowledge up to June 1956 and will be of great value both to clinician and laboratory worker.

[*Continued on p.* 135

**Your Baby and You.** By Dr. Winifred De Kok. (Pp. 221; illustrated. 2s. 6d.) London: Pan Books Ltd. 1957.

This is a book which gives a great deal of useful knowledge in a most concise and readable manner. The style is cheerful and practical and chapters well arranged. The early chapters discuss the beginning of pregnancy and give practical advice on making arrangements for confinement and the monetary grants available. Advice on the care of the body in pregnancy is good and the description and illustration of exercises clear.

The description of suitable clothing for the expectant mother is very helpful and the advice on baby clothing is very practical. The ailments of pregnancy are set out under clear headings, which are easy for reference and should be very helpful to a pregnant woman. The organs of reproduction and the physiology of labour are very clearly described and in a manner that should be quite acceptable to the young lay mind.

The advice to fathers shows Dr. De Kok's experience of dealing with young expectant parents, and the many problems which seem so large, but are easily solved with a little common sense.

The centre of the book has some delightful photographs to illustrate baby care in the early weeks of life—the advice is given here in a practical but humorous manner.

In the chapter on artificial feeding, the use of Milton for cleaning bottles and teats is mentioned. This is such a simple and efficient method that it seems a pity not to have given it complete and in correct detail instead of as a partial addition to the boiling bottles.

The latter part of the book should make a most complete guide for a young mother. Feeding is dealt with from breast feeding to full diet. The types of food necessary are given and also the management of the child if it does not feed well at any stage.

The behaviour both good and bad of children is most sensibly explained and the correct method of overcoming difficulties and apparent bad habits.

Vaccination and immunization are recommended in a manner which should appeal to most mothers.

Whilst reading this book one has the feeling that Dr. De Kok must have a great deal of practical experience and writes with a wonderful insight into the problems of young mothers. Her professional knowledge has becomes a background for her great and very human interest in mothers and babies which has caused her to write a book which can be recommended to any expectant mother as being most readable and full of sound advice.

**Synopsis of Tropical Medicine.** By Sir Philip Manson-Bahr. (Pp. xiii + 287; illustrated. 22s. 6d.) London: Cassell. 1957.

Sir Philip Manson-Bahr first published this useful little book in 1943, since which time there has been a second edition in 1952. This third edition is notable for the addition of a new section devoted entirely to listing the drugs and antibiotics used in the treatment of tropical diseases, together with the indications and dosages.

The bulk of the book, of course, is the author's well-known, painstaking synopsis of tropical diseases; the geographical distribution, epidemiology, ætiology, pathology, clinical features, diagnosis, treatment and prophylactic measures are among the many aspects covered. In addition to those diseases directly attributed to a variety of organisms ranging from viruses to helminths, there are also included sections on the nutritional and climatic factors affecting the health of man in the tropics, animal and vegetable poisons, and infestations by arthropods and leeches.

The enormity of the information contained in one relatively small volume has naturally necessitated the use of a rather drastic note-form type of presentation. It is unfortunate that some errors have escaped notice: thus it is rather confusing to be told on page 8 that the incubation period for malaria in man is seven to nine days while the figure given on page 10 is simply ten days. Again, the sudden mention of *Plasmodium inui* in the midst of a discussion on the differences between the pre- and exo-erythrocytic stages of human plasmodia might startle readers with little (or rusty) protozoological background. There is no reference to the fact that *P. inui* is a monkey parasite which is not transmissible to man and the impression is unfortunately given that *P. inui* must be included here because it represents a fifth human *Plasmodium!*

While most of the illustrations in the 8 Plates are good, some leave much to be desired. Those of intracellular aggregations *Leishmania* in Plate III, for example, could be taken for a poor representation of almost any intracellular organism, e.g. *Toxoplasma* or *Histoplasm.* There is also an inversion in the labelling of the drawings of this plate (Figs. 3 and 4): developmental, flagellated forms of *Leishmania* are labelled "Parasites enclosed within splenic pulp cells . . ." and vice versa.

Finally, the zoologist will probably be distressed by the implication of the heading "Arthropod, Fly and Leech Infections", on page 182, that flies are not arthropods!

Such errors as the above, however, are virtually insignificant when weighed against the

undoubted great value of this encyclopædia of tropical medicine. Sir Philip's book should find a place in the pocket of all medical men, as well as the parasitologists, in the tropic

**The Effects of Arts, Trades and Professions on Health and Longevity.** By Charles Turner Thackrah with an introductory essay on his life, work and times by A. Meiklejohn. (Pp. 50 + 238; illustrated. 25s.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

Charles Turner Thackrah must have been a remarkable man. His short life lay between the years 1795 and 1833, during which he achieved much. He lived in an age of great men, and was himself much influenced by his teacher, Astley Cooper, who had been a student of John Hunter. Qualifying at the earliest age possible at that time, namely at 21, he started practice in his home town of Leeds and was very shortly contributing to the even then ever-increasing volume of medical literature.

His chief claims to fame are the part that he played in the establishment of Leeds Medical School, and the production of his book entitled "The Effects of Arts, Trades and Professions in Civic States, and the Habits of Living, on Health and Longevity".

The story of his achievements is admirably told by Dr. Meiklejohn, and is made entertaining by the light that he throws on Thackrah's character. In fact the whole of the biographical essay makes excellent reading.

The main purpose, however, of the book is to reprint the second edition of Thackrah's chief work, and this in itself is eminently well worth while. Thackrah was the first man to collect together information about the effects of trades and occupations on a man's health and expectation of life, and thus to lay the foundations for prevention of disability, not only in industry, but also among the professional and leisured classes. The fact that there is nothing considerable that will surprise a modern reader of his pages emphasizes how much he was in advance of his time, and this will be seen to be true in many things, not the least being his appreciation of the importance of posture in leading to disability. His wisdom is demonstrated by his grasp of his problem as a whole, and his practical good sense is displayed by his insistence, oft repeated, on reasonable standards of living with adequate exercise and the avoidance of excesses.

This book should have a wider appeal than just to those who are interested in medical history, as in it can be read the thoughts of the enquiring, intelligent mind of a man who, living well over a hundred years ago, reached conclusions which have much point and relevance in this present day.

**An Atlas of Muscle Pathology in Neuromuscular Diseases.** By J. Godwin Greenfield, M.D., G. Milton Shy, M.D., Ellsworth C. Alvord, Jr., M.D., and Leonard Berg, M.D. (Pp. ix + 104; illustrated. 45s.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

The pathology of diseases of the musculature has never been regarded as a simple problem or even a straightforward one. Study of the stimulating Atlas will leave the reader in no doubt but that the subject is vastly more complex than he ever imagined. Indeed, the authors are explicit in their appraisal of the mysteries of their task. Gloomily they assert that at times one wonders whether a muscle biopsy is really helpful. But they finish in a more optimistic key. They discard a great deal of dead wood and in doing so they sedulously avoid such terms as "degeneration", "atrophy", "regeneration" and "necrosis" which, as they point out, imply more than they describe.

A new nomenclature for dealing with the structural changes is therefore adopted. The first part is concerned with these histo-pathological reactions. The text is kept commendably brief and clear, and the argument is presented mainly by way of a rich series of beautiful illustrations, many of them in colour. In the second part of the book, the authors attempt to formulate a clinico-pathological correlation. This proves a difficult undertaking for even a clinical classification of neuromuscular diseases turns out to be a tentative and not altogether satisfying matter. We are interested to discover that there exist important discrepancies between clinical data and histological observations. It is obvious that the subject of neuromuscular disorders is still a very imperfectly documented chapter in neurology. The authors have done well in presenting so succinctly a fascinating *aperçu*. It will surely stimulate practising neurologists and their pathological colleagues to explore more deeply into these poorly charted waters.

**The Clinical Examination of Patients with Organic Cerebral Disease.** By R. Klein, M.D., and W. Mayer-Gross, M.D., F.R.C.P. (Pp. xiii + 96; illustrated. 15s.) London: Cassell & Co. Ltd. 1957.

There is admittedly a need for a clinical manual dealing with the systematic examination of a patient with organic affections of the brain. The very fact that no such treatise has been undertaken up to now is possibly significant in itself. Various experienced neurologists,

[*Continued on p.* 137

with particular interest in a knowledge of problems of highest level cerebral dysfunction, have been known to have pondered the matter seriously only to have decided finally that the subject is best avoided. The two present authors are therefore to be congratulated upon their courage in grasping this particular nettle. Their armamentarium of clinical tests is a good one but perhaps they have tended to gloss over some of the difficulties—which are in themselves an integral manifestation of the disordered behaviour in their cases. For example, the question of what a patient can do or cannot do in a given test-situation tells us only a little. What is much more significant is the way the patient goes about the task. This cannot be adequately evaluated without a full-dress description. Case-taking must therefore be of necessity a laborious and detailed procedure, and short-cuts, schemata, and questionnaires are inadequate. The patient's hesitancies, inconsistencies, slowness, changes of mind, perplexity, and display of emotion are much more meaningful than an eventual correct answer or performance. This applies to the patient with aphasia, apraxia, "agnosia", and indeed almost any other cerebral disorder of perception or of symbolic thought.

These then, in the briefest of terms, are some of the pitfalls attendant upon the examination of patients with organic cerebral defect. As the clinical snares have not been made clear by the writers at the very outset, the value of the present schema of tests suffers. It is uncertain for whom the manual is written; if for an undergraduate it is too recondite, and if for a neurologist it is inadequate. Perhaps it can best be summarized as being written for young psychiatrists by psychiatrists of experience.

As far as they go, the clinical procedures form a useful *aide-memoire*, for complex and manifold as are the manifestations, they may elude the attention of those who do not handle such patients every day. Certain errors and points for criticism can be picked up here and there; e.g. Koh's for Kohs' blocks; and Bey for Bay. The English style is halting, and in places it transgresses the canons of accepted usage. The term "residual utterance" is an unorthodox one in neurology. The insecure status of the agnosias is perhaps not sufficiently stressed. Disorders of tactile perception are sketchily dealt with, and although tactile agnosia is discussed, the commoner astereognosias are by-passed. There is a useful bibliography but with perhaps undue emphasis upon the German literature.

**A Manual of Human Anatomy.** By J. T. Aitken, M.D., G. Causey, M.B., F.R.C.S., J. Joseph, M.D., M.R.C.O.G., and J. Z. Young, M.A., F.R.S. Vol. III—Abdomen and Pelvis. (Pp. viii + 135; illustrated. 12s. 6d.) Vol. V—Central Nervous System. By J. T. Aitken, M.D., D. A. Sholl, B.Sc., and J. Z. Young, M.A., F.R.S. (Pp. vii + 140; illustrated. 12s. 6d.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

With their companions, these volumes provide a complete guide to the dissection of the human body. They are brief and factual and cover reasonably adequately the needs of the medical student in the dissecting room. As a purely factual and limited description of human anatomy they must be praised, and their brevity is highly commendable. The student dissecting for the first time might well find the book helped him very little in the identification of structures in the body and would need a great deal of personal supervision and assistance to make his dissection comprehensible. In the part devoted to the abdomen and pelvis the illustrations are good and there is a practical guide to surface anatomy. The central nervous system is more comprehensively described and notes on its development in this type of manual seem ectopic. Much of the material here is devoted to a description of slides from one particular school, and the text would need some revision before it is generally applicable. The series is most attractively produced in a form suitable for the dissecting room, and represents a notable advance in the simplification of anatomical teaching.

**Medical Negligence.** Being the Laws of Negligence in Relation to the Medical Profession and Hospitals. By the Right Hon. Lord Nathan, P.C. (Pp. xxxii + 218. 35s.) London: Butterworth & Co. (Publishers) Ltd. 1957.

Lord Nathan, in his preface, gives two reasons for this book. "In the first place, I have sought to present, in a form which it is hoped will be useful to the legal practitioner who is called upon to deal with such matters, an objective and comprehensive statement of the law relating to the liability of medical practitioners and medical institutions for professional negligence." Your reviewer, writing as a lawyer, agrees that he has succeeded in his first purpose. The references to the numerous cases of medical negligence in the courts of the Dominions and of the United States of America add to its utility to the lawyer. It is comparative law at its best. He explains the second purpose in the following paragraph: "At the same time I have been anxious to avoid, as far as possible, the unattractive characteristics of so many legal textbooks—obscure language, voluminous footnotes and the rest—in the hope that the book may prove acceptable to members of the medical and nursing professions and to hospital administrators as providing in a readable form *some guidance*

*on the nature of their professional responsibilities and the risks which affect them in the course of their work.*" (The italics are mine.)

The author in Chapter I—Introductory—on pages 4 and 5 makes certain observations regarding medical negligence actions in general and correctly assesses the three main factors for the very substantial increase in the volume of such actions. They are the introduction of the National Health Service Act, which has effected a subtle change between the medical man or hospital and the patient, the introduction of the Legal Aid Act and the modifications in the Law relating to the liability of hospitals for the acts of their staff (Chapter 5). Your reviewer, writing as a doctor, finds it an illuminating admission by the author, whose political allegiance he knows quite well, that the National Health Service Act has altered the doctor-patient and hospital-patient relationship. The sting is in the tail of this introduction. "It is perhaps inevitable that there should from time to time be cases in which the standard of skill and care exacted by the judges may appear to the medical profession to be excessively high." As a doctor, your reviewer strongly disagrees with the author that "it may be some consolation to reflect that a Court which exacts a high degree of skill and care from a particular defendant is in effect paying tribute to the high standards maintained by the medical profession as a whole."

The *professional responsibilities* of the doctors have not changed since the days of Hippocrates, modified by the Declaration of Geneva, which was evolved by the World Medical Association in 1951. The *risks* which affect them in their work have changed. It is not true to assert that there has been no change in the general law of negligence as it affects the medical profession. I quote Croom-Johnson, J., in *Best v. Samuel Fox & Co* (1950), 2 All. E.R. 798: "The law of England is a living law. It develops and must develop according to change in social life and social outlook." Lord Justice Denning recently asserted that the law is simply a means, albeit an uncertain process, whereby society works out its purposes. In the last fifty years we have seen revolutionary changes in the social structure of this country, especially since the end of the last war. Inevitably the enormous growth in the medical services has made them become of increasing importance in the social structure. The creation of the Welfare State has produced legal problems which are inextricably intertwined with this era of profound change. Where does the doctor stand in this elaborate and uncertain legal process whereby society works out its purpose? He now lives in a world of greater legal risks by reason of the present nature of the judicial process which has enlarged and extended the scope of medical negligence by the very exacting and often onerous standards of medical care and skill.

In spite of these criticisms I must congratulate the author and his collaborator on a concise and well-written book on a very important subject. The case law is extensive and the salient points in the judgments clearly emphasized. I strongly recommend all doctors and hospital administrators to read it. The book has a very useful index.

**Principles of Renal Physiology.** By Homer W. Smith, A.B., Sc.D., M.S. (Pp. x + 237; illustrated; 40s. 0d.) Oxford University Press. London: Cumberlege. 1956.

This little book of some 237 pages gives the current views of renal physiology in a condensed form.

The author gives the anatomy and an excellent short historical note on the theories of renal function before starting to deal chapter by chapter with each of the functions of the kidney. The various principles governing the determination of filtration and reabsorption rate, and renal plasma flow are given in detail. The latter chapters are mostly concerned with the specific problems affecting the kidney, such as water and electrolyte control, together with the formation of ammonia and control of the acid-base equilibrium. In fact all the aspects of the kidney are fully covered.

In the Appendix, which is the most interesting section of the book, a description of the structure of the glomerulus, proximal and distal tubules, as seen by electron microscopy, is given. This is particularly well done, and clarifies the previous literature on the subject. The analytical methods used for determining the renal clearance, filtration rate, and renal plasma flow are given in full with alternative methods.

The principal difficulty of this book is that it is not quite clear for whom the book is intended. In this country the pre-clinical student would hardly find it necessary to go into such minutia of renal function as given here. Nevertheless, it may well fill the want of the postgraduate student who wishes to bring his knowledge up to date, particularly those sitting for the Membership of the Royal College of Physicians—or those who wish to study current renal problems before undertaking research.

At the end of each chapter a problem is set to the student, which is perhaps a little irritating, but no doubt will be found useful by the student sitting for an examination. At the same time the list to guide future reading and the analytical methods will prove valuable, and will serve as an introduction to a most intricate subject, since the subject matter is clearly put out and easily assimilated.

## SYMPOSIUM ON OPERATIONAL RESEARCH IN THE NATIONAL HEALTH SERVICE

Dr. J. N. Morris (London): *Introduction*

The subject of this symposium may be defined as *the scientific study of the working of the National Health Service with a view to its improvement*. "Operational Research" was invented before the war in connexion with radar, to analyse its translation from theory to practice—i.e. what actually happened when radar was tried out in real life. An institution like the National Health Service, it is safe to assume, does not do all it is supposed to do, and does things it was never intended to do. Obviously there is need and scope for investigation but, so far, there is far less of this than there might be. Meanwhile, operational research has developed rapidly in industry and elsewhere, and in the process has acquired some particularly striking statistics. There is a lot to be learned from these studies: for example, the problems of economic stocking and the flow of materials through a factory, or of the flow of iron ore from ship to furnace, or of traffic on road and roundabout have, technically, much in common with medical-administrative problems already tackled on the flow of out-patients in general hospitals (Welch and Bailey, 1952) or of inpatients through mental hospitals (Kramer, 1957).

Three stages may be described in operational research. *First*, the estimation of needs; *second*, analysis of services in action; *third*, appraisal or evaluation of their success. All these present serious difficulties, but it is one of the advantages of this type of study that modest and simple inquiries may yield immediately useful information, useful to the administrator and to the community in helping them to make the right decisions in particular situations. It is, however, important to ask questions that are founded on some knowledge of what the Health Service is about; too little of such appreciation reduces the value of some of the studies that are being made.

The classic example of estimation of need in advance is that by the Social Survey on the Medresco Deaf Aid (Wilkins, 1949) to which Mr. Moss will refer. There is little doubt that some of the violent criticism which the National Health Service had to meet in its early years could have been reduced, or even avoided altogether, if similar studies had been done on the need for spectacles, dentures, &c., so that the government could have used and publicized more realistic estimates of needs and costs. To-day there are many difficult questions. For example: supposing maintenance anticoagulant therapy is proven of value in coronary heart disease, what clinical and pathological service will be necessary to discharge the responsibilities of the National Health Service? How are the needs for cardiac surgery assessed at the Ministry? Presumably they will differ regionally and locally, for example with the incidence of juvenile rheumatism some years ago. What are the unmet needs for specific treatment of depression in the elderly? In general, with mental illness no realistic assessment of needs is possible as yet; which perhaps does not matter too much since we are a long way from being able to satisfy demands that are already vocal and pressing upon us. In this field, even more than in physical disease, it must be expected that the provision of services will uncover needs, "create" demand, change public perception of what is tolerable (Koos, 1954).

In the analysis of actual services, Dr. Martin will describe the use made of the experiment of opportunity offered by a new housing estate. Dr. Lee will give an example of the kind of difficulty that is involved in providing a meaningful statistical analysis of hospital staffing (Lee *et al.*, 1957). How far do the exceedingly important factors about which there is not, and often cannot be, statistical information affect the picture presented of gross inequality in the staffing of teaching and non-teaching hospitals?

Attempts to appraise the quality and to evaluate the success of services present most difficulty, and often go by default in favour of studies of bed-turnovers, man-laundry-days, &c. (Lee, 1958). The methodology may be readily available, e.g. in clinical therapeutic trials and the actuarial life-table. To mention only two instances, as yet there is little evidence that mass tonsillectomy is worth while—or has been abandoned; and the child guidance movement is still little more than an act of faith.

In view of the changing character of health problems, of medicine, and of health services,

it might be expected that a great deal of operational research would be going on. This is not the case. The Guillebaud Committee (1956) recommended that the development of these inquiries should be based on the Ministry of Health. Although the recent development of an energetic and enterprising Statistical Division at the Ministry is much to be welcomed, it is doubtful whether the Ministry is a suitable centre for many of the studies. The Ministry is too involved in problems of medical politics and finance to be a good base for the research into, say, the quality of general practice. Moreover, many of the problems needing study cross government-departmental boundaries, and a Ministry of Health research group would be badly placed to examine the problems of industrial medical services. Great foundations are interested in this field, and the King's Fund and the Nuffield Foundation have made notable contributions; the latter's researches (1955) into the design and functions of hospitals, it is encouraging to learn, have now been placed on a permanent basis. However, it is clear that the main responsibility for operational research in the future will devolve on the academic departments of social medicine in collaboration with their colleagues in the social sciences. It must be faced therefore that these inquiries inevitably raise controversial issues which may be viewed very differently by the administrator in the government department and the academic investigator outside. It would be idle to fancy that these differences can easily be reconciled. This is merely one aspect of a central problem of our times, the relations of science with government.

The improvement of the National Health Service is an objective which commands general support and there is probably more general agreement about it than on any other comparable issue of social policy. Operational research, which means for the most part an application of epidemiological methods (Morris, 1957) has a part to play in attaining economy and efficiency, in the optimum use of scarce man-power. Above all, it can help in discharging the responsibility of the medical profession for the quality of medical care.

**Dr. F. M. Martin** (Edinburgh): *Some Problems of Health and Medical Care on a New Housing Estate*

This paper presents some of the results of a study of a new housing estate carried out by a group of workers in the London School of Hygiene under the direction of Dr. J. H. F. Brotherston.

The estate which stands in Hertfordshire is one of a dozen out-county estates built by the London County Council during the post-war years. It contains more than 4,000 families and has a total population of between 17,000 and 18,000. Most households, as is common in new housing areas, consist of a married couple in their thirties and a pair of children of school or pre-school age. About two-fifths of the entire estate population at the time of our enquiries were below the age of 16 and only 12% were over the age of 45. Two principal factors determined a family's degree of priority on the housing waiting list at the time the estate was built. The more important of these was overcrowding and the other was certificated ill-health. We found that medical certificates in support of an application for re-housing had been submitted by half the families living on the estate. These had all been scrutinized by the Council's Medical Officers and four-fifths of them had been approved. The most common diagnostic groups as indicated by the certificates were lower respiratory conditions, nervous disorders, tuberculosis and upper respiratory disease, accounting respectively for 17, 14, 12 and 8% of all certificates. The use of medical judgments seems to derive less from knowledge of the beneficial effects of re-housing than from the need to employ a system of priorities among cases which cannot on ordinary housing grounds be differentiated one from another, by applying a criterion

which, though often of dubious relevance, carries an authority which our culture places beyond question.

The population was drawn predominantly from the ranks of skilled manual workers, and although it carried only a thin layer of black-coated workers (perhaps 10% of the total) its complement of semi-skilled and unskilled manual workers was proportionately smaller than that of London or of the country as a whole. It is notoriously difficult to secure accurate information about incomes but our evidence, such as it is, strongly suggests that the families who moved to the estate were on the whole a good deal better off than the general run of the Council's applicants for new housing. It is, in short, a group which might be expected to adapt itself to a lower middle-class pattern of residence, of income distribution and of family aspirations more easily than many other segments of the working class, though by no means painlessly.

Can any distinctive features be observed in the sickness experience of the estate population or in their usage of health services? In purely quantitative terms the volume of demand for the general practitioner's services does not differ very much from that established for urban practices by Backett, Logan and others. The reduction in the consultation load arising from the virtual absence of old people from the estate is counterbalanced partly by the large number of children and partly by the sizable number of people re-housed on the grounds of ill-health. Infectious diseases play an exceptionally large part in the work of the general practitioner as do symptomatic and ill-defined conditions. Many of the latter appear to have a large psychological element. Thus anorexia, debility and undue fatigue, and headache are all more common than in any of the twenty-six practice-years studied by Logan, while other conditions such as insomnia and vertigo are well in the upper half of the range of consultation rates which Logan reports. Among the digestive conditions it is interesting to see that although consultation rates for gastric ulcer and for dyspepsia correspond very closely with expectation on the basis of age and sex, the rate for duodenal ulcer is nearly three times the expected figure and is exceeded in only one of Logan's twenty-six practice-years. Migraine among the diseases of the nervous system and urticaria, hay fever and asthma among the allergic conditions, all have consultation rates which fall in the top third of the range observed by Logan. What these conditions have in common, of course, is that they are all fairly strong candidates for classification as psychosomatic. The frank psychoneuroses all had consultation rates above the expected figures—twice as high in the case of anxiety neurosis.

It is difficult to say very much about distinctive features in the use of hospital services by people living on the estate as most published studies do not relate hospital admission or out-patient consultation rates to any defined population. The mental hospitals are an honourable exception and here it has been possible to compare admission rates over a six-year period with a national standard. During the whole of this period admissions were about 50% higher than would have been predicted on the basis of age and sex composition. Comparison with Greater London rather than national admission rates reduces the discrepancy but only slightly. On the other hand, no allowance has been made for the fact that the estate contains so few unmarried adults and so few unskilled manual workers—both groups with disproportionately high mental hospital admission rates. The observed excess appears to be due mainly to a high incidence of neurotic depression among middle-aged women.

As far as other hospital admissions are concerned there do not seem to be many outstanding features. The high—though not unparalleled—frequency with which patients were referred to hospital out-patient clinics can best be understood in terms of the impact on a group of relatively inexperienced general practitioners of a population which by definition had more than its quota of health handicaps and with no provision (except in cases of tuberculosis) for maintaining continuity of care or even for transferring essential information. In the circumstances it was inevitable that they should make generous use of consultant services if only to establish a base line.

The infant welfare services are very widely used and appear at first inspection to overlap considerably the work of general practitioners. The important and distinctive service provided by the clinic doctor was to listen with sympathy and understanding and thereby provide some substitute for the traditional supports of the family and the neighbourhood which were so clearly lacking.

New housing areas would seem to offer ideal testing grounds for experiments in collaboration between the branches of the National Health Service. The planning of the estate coincided with the planning period of the National Health Service. The London County Council reserved a large site for a health centre and the Hertfordshire County Council planned an elaborate structure to accommodate general practitioner and local authority services. However, no doctors practising in neighbouring areas were prepared to commit themselves in advance to paying substantial rents for consulting rooms in the

new centre, and the plan was dropped with no more modest alternative being provided. Thereafter, local authority and general practitioner services developed independently for a few years and with minimal contacts until in due course the suggestion was put to both groups that they might consider investing in new premises for their joint use. After long discussion dissatisfaction with grossly inadequate existing accommodation triumphed over memories of an earlier rebuff on the one hand and fears of marauding practitioners on the other. Work has begun on a group-practice building and on new local authority premises. These have been designed by the same architect in such a way that the two buildings, though legally separate, form an architectural unity.

We have been impressed by the need for special arrangements for the provision of health services on new housing estates of this kind, having regard to the size of the community, its special nature—particularly if priorities on health grounds are awarded—and the supportive functions which community services have to provide to substitute for the loss of the traditional supports of family and neighbourhood. Situations of this kind present distinctive difficulties which generally include local suspicion and hostility to the new community and a failure to recognize its problems. This is particularly understandable when services whose provisions are already inadequate or hard pressed in the face of a rising demand have these new needs thrust upon them. The administrative rigidity of the National Health Service and some of its divisions of responsibility—for example in the provision of health centres—also make it difficult to take effective administrative action in advance of the population and its demands. There are, however, some aspects of the situation which might have been turned to very good account—its fluidity in the early stages, and the malleability of behaviour produced by the lack of any clear-cut expectations in the re-housed population. It seems to us that this new estate offered to the National Health Service an opportunity for imaginative experimental planning which, so far from being grasped, was in fact scarcely even recognized.

**Mr. Louis Moss** (Government Social Survey): *The Use of Survey Techniques in Connexion with the Operation of a National Health Service*

This paper does not attempt a general review of all the possible uses of survey techniques nor even of all the past actual uses of survey techniques in connexion with public health services. It is limited to a summary account of some of the ways in which survey techniques have been used in this country on health service problems by the Government Social Survey.

We can say that, in general, survey techniques can be used to do two main things for a national health service. They can help us (1) to obtain an overall picture of the problems which the service is designed to help, or (2) to examine the efficacy of the methods and organization used to deal with any selected part of the whole field. The term "operational research" may fairly be applied to both uses.

*Survey of Sickness*

A good example of the first use is the Survey of Sickness enquiry which was carried out for the Registrar-General over many years in this country. The Survey of Sickness had two purposes. Its first purpose was to give an overall picture of the level of incapacity and the range of complaints in the population as a whole. Its second purpose was to provide a picture of the use made by those with complaints of different sections of the medical service.

The method used is to sample the whole population and, by means of direct interview in which individuals are taken through the whole range of morbidity and possible medical attention, to obtain an overall picture of what has happened in a limited period of time [1]. Broadly speaking, by means of this technique we screen the whole population. Clearly the results achieved are very closely related to the fineness of the screen used and this may vary according to the resources which are available for the work. The Cornell Medical Index, for example, applies a much finer screening process than the one used in our Survey of Sickness.

In any study of this sort the nature of the screening process should relate to the degree of detail which is thought to be operationally useful. Clearly it is not to be expected that ordinary members of the public will be able to diagnose illnesses which only thorough medical examination can bring to light [2]. The screening process which such a study carries out is therefore unlikely to be on a very profound level.

Whatever the limitations of the data for diagnostic purposes it seems to be suitable for very many purposes of organisation and administration in the public health field. The limitations of the method seem to be fairly clear. It may therefore be useful to summarize briefly what the method enables us to do that is not otherwise possible. In the first place efficient sampling can give us a comprehensive picture of the whole population, of all known illnesses and of all uses of health services in very broad terms. In this sense it covers a much wider field than data related only to those who are covered by insurance schemes

or by those who attend hospitals. It is likely to be more comprehensive and representative of the general population than information derived from doctors keeping voluntary records. Secondly, since all continuing records are likely to be limited it is very often difficult to derive detailed classifications of the patients concerned from them. For example, in trying to derive the economic group of patients covered by administrative statistics the statistician is often forced to use very broad economic indices of the district in which they live. Since Survey of Sickness data are obtained directly from patients it is possible to obtain more detailed information about the social and economic context of illnesses and use of health services. Because this information is obtained directly it can be more precise than data available from mass records. It may be said, therefore, that whilst Survey of Sickness information tends to be broad and general in the morbidity field it can be more detailed and explicit on the social and economic factors, or what might be called behavioural factors, involved in illnesses and medical attention than other forms of data. It can clearly be much more comprehensive and representative than other forms of data.

It may be asked what operational uses can be served by the information derived from this kind of survey [3]. If such a survey continues over time we can derive data which enable us to make statements about changes between two points in time. Thus Dr. Logan of the General Register Office used Survey of Sickness data to study changes in illness, incapacity and medical attention among adults in the year before and after the inauguration of the National Health Service [4]. Perhaps one of the most important contributions of this type of survey is that it enables us to see how the total amount of medical care and attention is distributed between different sections of the population. In a very useful account of the kind of data produced by the Survey of Sickness Gray and Cartwright [5] have shown that the weekly medical consultation rate per 100 persons in 1950 varied from 7·6 in those aged from 21 to 34 to 16·7 in those aged from 65 and over. Similarly, the weekly medical consultation rate varied from 8·9 per 100 persons in the higher income groups to 16·0 per 100 persons in the poorer sections of the population. They showed, too, how the rate of consultation was related to the percentage of consultations resulting in a prescription.

Survey of Sickness type data enable us, therefore, to study changes over time and, by implication, the relationship between these changes and administrative actions of one sort or another, changes in policy and so on. These changes may be studied not only in so far as they affect the population as a whole but also in terms of the sectors of the population affected. By using data about the attention received by patients we can say a great deal about the work done by doctors, the distribution of doctors' time between different sectors of the population and in relation to different forms of incapacity.

However, survey methods cannot only be used to describe existing situations; they can also help to plan developments.

*Forecasting Change*

After the National Health Service in this country was set up experience showed that demand for some of the facilities provided was much greater than had been anticipated. In only one field was an attempt made to predict the new level of demand. This was in connexion with the Medresco Hearing Aid. The M.R.C. Committee on Deafness asked the Social Survey to try to measure the prevalence of deafness in the civilian population and to make some estimate of the number of Government hearing aids likely to be required. Wilkins used the basic framework of the Survey of Sickness for his attempt to answer these questions [6]. Using a scale of questions devised by an American researcher which related social disabilities to measured hearing losses, Wilkins was able to show what proportions of the total population were likely to be suffering from different levels of deafness. By the use of additional questions he was able to make estimates of the likely demand for hearing aids on a series of different assumptions.

It is useful to continue with the same example in order to illustrate the second main contribution which survey techniques can make to the operations of a health service as a going concern.

*Studying the Use and Servicing of an Appliance*

After the Medresco hearing aid had been available for some time the Social Survey was asked by the Ministry of Health to study the use actually made of the hearing aid with a view to making any improvements which experience had shown to be necessary and possible. Gray has given an account of some of the results of this work [7]. He sampled those who had actually been issued with the aid, obtained detailed information from them about the use made of the aid and the circumstances under which it was used, and then went on to investigate a series of practical problems connected with the running of the service, such as the provision of batteries, servicing and so on.

By showing under what circumstances the hearing aid was worn Gray was able to make clear what actual working conditions the aid was having to meet. This information was

also useful in showing the conditions under which the new transistor aids would have to work. An examination of the repairs needed and the number of visits made for repair of the aids showed how much time was involved in having them serviced and the relative frequency of different types of repair.

Special meters were used by the interviewer to take readings from the batteries actually in use at the time of the interviews. It was thus possible to determine whether patients were using their batteries to the utmost. A comparison of the hours of use actually obtained with that theoretically possible if the batteries are used fairly rapidly showed that, where batteries were used only intermittently over a long period, battery deterioration resulted in appreciable loss of capacity.

With the use of information of this sort it was possible to suggest ways by which the servicing and repairs arrangements could be changed to the advantage of the patient and the economy of the service. This study I think is a classic example of operational research. I would note that the basic information came from first-hand contact with and observation of patients. The detailed questions were, of course, worked out in close collaboration with the technicians and administrators concerned with the service. In this way it was possible to ensure that the data collected would have a direct bearing on problems which were in the minds of the administrators.

*Studying the Working of a Policy*

For a further example of a study designed to check the operation of a health service activity I shall turn to a completely different field. For many years we have had a welfare foods policy and Fothergill [8] carried out a series of surveys at the Social Survey designed to show actual food intakes of special sections of the population. This he did by selecting samples of these special sections and persuading informants to weigh all foodstuffs taken in a given period. These weights were then transformed with the use of conversion tables into nutrient quantities. By use of this kind of material, it was possible to show what the facts were about the nutritional condition of the sections concerned. Within this framework it was possible to answer some questions of operational importance. For example, if the whole diets of children of a certain age were known and the nutrients derived from different kinds of foodstuff could be shown in the manner I have just indicated, then it is possible to answer the questions: Would the diets fall below necessary minimum levels if there had been no intake of welfare food? What contribution is made to vitamin-C levels by fresh fruit or by orange juice provided under the welfare food scheme? Other surveys in this field gave answers to such problems as: Which sections of the population get their welfare foods from one source rather than another? Did the change in the method of distribution of the welfare foods affect the numbers of people taking the welfare foods? [9] Which sections of the population appear to make least use of the welfare food scheme? And so on.

I would now like to give one further example in which survey techniques have been used to provide experimental evidence about the possible effects of suggested changes.

*Providing Experimental Evidence of the Effects of an Innovation*

The work of a Nuffield research group under the leadership of H. A. Goddard led to certain conclusions about the organisation of hospital nursing work. In particular it was suggested that there were many advantages to be derived from what is called "group assignment" as contrasted with the older method of "work assignment". Under "group assignment" two or more nursing teams in the ward each undertake the nursing care of a small group of patients, while under "work assignment" all the nurses in the ward perform specific tasks for all the patients. Advantages were suggested both for patients and for the training of nurses as well as in maintaining the interest of nurses in nursing duties. It seemed to be important to put these suggestions to some practical test. The Social Survey were asked by the Standing Nursing Advisory Committee to devise experiments with this end in view. The co-operation of four hospitals was obtained and appropriate studies were made in a medical and surgical ward in each of the hospitals. Briefly, the studies designed by H. W. Willcock involved before and after observations in these eight wards. A group of nurses was trained by the Social Survey in direct stop-watch observations. A sampling system was devised by which nurses' time was sampled in half hourly periods throughout the working day in the selected wards and spot observations taken at 15-second intervals. All wards were studied by this method and a detailed account thus obtained of all activities taking place in the ward, the nurses carrying them out, the time taken to carry them out, and the condition of the patient concerned. After these preliminary observations had been made the wards concerned were reorganized on a group assignment basis and the new system put into operation. When the hospitals concerned felt that the new system had been working long enough, a further week's observations using precisely the same techniques were made. Comparisons were thus possible of the

whole range of work carried out within these hospital wards before and after the new method of hospital organization. Willcock was thus able to show how the time devoted to different kinds of activities by different levels of nurses had changed. With this information as a background it was possible to see whether or not the different advantages expected from the group assignment system had been achieved. For example, Willcock showed that under group assignment there was a change in the kind of patient on whom attention is concentrated. Those in what he called "Dependency state 2: mainly a state of recovery prior to being allowed out of bed" got a great deal of the additional nursing time available under group assignment. First-year student nurses spent only 21% of their time on technical nursing procedures under work assignment but 30% under group assignment. A detailed examination of the data showed that they were not undertaking duties outside their competence.

The individual staff nurse spent more of her time under the new system with both third-year and junior student nurses: the increase was from 104 minutes per 1,000 minutes under work assignment to 154 minutes per 1,000 minutes under group assignment.

It was relevant to this study to find out how the nurses, patients and doctors felt about the new system and to consider their subjective reactions together with the objective data obtained from the time sampling studies. One of the methods by which this was done was to obtain details of complaints about their hospital stay from patients who had been in the wards during the two periods concerned. It was possible to show that the level of complaint dropped sharply under group assignment. Although the number of criticisms made under both systems was relatively small, there was a reduction of more than a quarter under group assignment. This lower level of complaint covered the whole field of complaints.

*Conclusion*

The surveys I have referred to cover a rather wide range of techniques: we have used interviewing methods, we have obtained objective data about the use of appliances from our own observations, we have persuaded sections of the population to make detailed records of their diets, and we have observed with time and motion study methods the activities of nurses inside hospital wards. This range of techniques may be surprising to those who think of social surveys only in terms of public opinion studies. I would not want for one moment to minimize the importance of opinion studies for any public service, especially one which claims to be run on democratic lines. At the same time it is clear that many of the operational problems which arise in connexion with public health services require a wider range of information. The techniques which it is right to use on each problem are those which can produce the appropriate data and this varies from problem to problem. All the data collected in the work described, however, have come from some kind of direct contact with the population concerned; none of it could have been obtained from existing records thrown up by the day-to-day operation of the service concerned. Not only must the questions asked be useful ones, their detail and ordering is of great importance, and so is the method of asking and recording [10]. The more detailed the information required the more important it is to use fieldworkers who have been trained to interview, observe and record. All the information used in these studies was obtained by the staff recruited and trained by the Social Survey.

Data are only likely to be useful for operational purposes if the questions and observations which produce them are defined in the light of operational problems and methods. For information to be operationally useful, therefore, it must derive from studies designed in close working contact with those involved in the operations. All the studies referred to here have been worked out on this basis. In this sense they are examples of the use of research methods to assist working operations.

## SYMPOSIUM ON EVENTS IN PREGNANCY IN RELATION TO DISEASE AND DEFECTS IN THE INFANT

**Dr. Alison D. McDonald** (London):

Until recent years it was commonly believed that congenital malformations were genetically determined, but the possible role of environmental factors is now receiving more attention. Animal experiments have shown that pregnant females exposed to anoxia and to a wide variety of other agents—chemical, endocrine, dietary, actinic, and mechanical, may give birth to defective offspring. The nature and frequency of defects produced in this way are often related to the stage of gestation at which the noxious agents are administered. Some malformations undoubtedly result from arrested growth of a tissue, but as has been pointed out by Patten (1957), this mechanism does not explain those apparently due to overgrowth or failure of tissue absorption. It is still not known whether any of these animal experiments have any relevance for man, and rubella is still the only environmental agent which it is possible to incriminate. However, there has been comparatively little epidemiological study of many events in pregnancy that might conceivably be important.

Of the various insults that bring about defects in experimental animals, anoxia and mechanical stress are two which could also occur during normal human pregnancy. Though gross dietary deficiencies in times of war and famine have not apparently been associated with an increase in congenital malformations, excessive vomiting of pregnancy could result in temporary dietary deficiencies of perhaps a different nature. There is no convincing evidence that specific infectious diseases other than rubella cause defects, but the importance of less obvious infections, including those of the upper respiratory tract, has not been explored. Lack of seasonal and long-term variation in the incidence of defects, however, suggests that such infections could hardly account for a high proportion of the total.

It is probable for embryological reasons that most defects originate during the first 12 weeks of fœtal life. Retrospective investigations undertaken at the end of pregnancy are of limited use in the study of this period as a mother's recollection of events six or more months earlier is liable to be inaccurate and influenced by her knowledge of the outcome. The prospective method although laborious is free from these problems, and provides comparable information on a large number of normal births.

In a prospective study that I began in Watford and St. Albans in 1952, results of which are described fully elsewhere (McDonald, 1958) some 3,300 women were questioned at the time of booking for a confinement, about events in the first 12 weeks of pregnancy. They were then followed until the outcome of the pregnancy was ascertained. So far only defects observed at or soon after birth have been available for analysis. Many important defects will therefore have been missed, but it may be possible to have the children examined again later. In this series there were 122 congenital defects—50 somewhat arbitrarily classified as major and 72 as minor—68 spontaneous abortions, and 74 stillbirths or neonatal deaths without congenital defect.

The mothers of infants with minor defects did not appear to differ from those of normal infants in any of the factors examined. In the remaining three groups—major defects, abortions, and stillbirths or neonatal deaths—no significant difference was found in respect of a number of factors, but in others certain differences were noted. There was no indication that marked vomiting influenced the outcome, nor were events which might cause fœtal anoxia, e.g. fainting, general anæsthesia, and vaginal bleeding, more common among mothers of infants with major defects. On the other hand there was an association between vaginal bleeding and stillbirth or neonatal death. Confessed attempts at abortion and maternal injuries were equally common in all groups.

Chronic disease was slightly more common among mothers of infants with defects, but on further analysis the difference was found to be due to an excess of pulmonary tuberculosis and of anæmia. The relationship with tuberculosis, which was statistically significant, was true not only for the pregnancies studied but also for previous pregnancies. Anæmia (hæmoglobin value of less than 80%) was more frequent among mothers in all three groups with an abnormal outcome than among mothers of normal infants, significantly so in the group of stillbirths or neonatal deaths.

No infants with major defects were born to any of the few women in the series who had a specific infectious disease, but there was a statistically significant excess of acute febrile illnesses, mostly involving the respiratory tract, in mothers of infants with major defects.

There was also a suggestive relationship between acute illnesses, febrile and non-febrile, and both abortions and stillbirths.

No evidence was found that heavy work was related to abortion or stillbirth but a statistically significant excess of mothers of infants with major defects had been engaged in work which they described as heavy—particularly laundry work.

The raised incidence of infants with major defects among mothers with pulmonary tuberculosis, acute febrile infections and heavy work, I think deserves further study. It should not be difficult to determine the frequency with which women with pulmonary tuberculosis give birth to defective babies and not impossible to do the same for a large group of women engaged in heavy laundry work, but the problem of the minor febrile illnesses is less straightforward. Advantage might be taken of the fact that most women have blood taken in the third and fourth month for Wassermann and Rh tests and surplus serum might therefore be available for testing against various viral antigens.

**Dr. R. G. Record** (Department of Social Medicine, University of Birmingham):

*Environmental Influences in the Ætiology of Congenital Malformations*

It has long been suspected that the pre-natal environment may have an important influence in the causation of congenital malformations and support for this view was provided by the discovery that maternal rubella in early pregnancy may lead to certain defects of the eye, ear and heart. Additional evidence from laboratory investigations has shown that in some animals malformations can be induced by feeding with vitamin-deficient diets, and by over-dosage with vitamins and by other means. It is not known what relevance these experiments have to the problem of human malformations and they do not seem to provide any explanation for the results of the few epidemiological studies that have been made.

There have been several attempts, mostly by retrospective enquiry, to relate human congenital malformations to disorders of pregnancy, but, except in the case of rubella, the evidence is scarcely convincing. There are serious objections to the retrospective method, and it may easily give rise to false conclusions unless suitable precautions are taken. The possibilities and limitations of the method can be illustrated by reference to the results of some investigations which have been carried out in Birmingham during the last ten years. In epidemiological studies of certain malformations, we enquired of the mother, some time after the birth, whether her pregnancy had been complicated by any disease or unusual event. The more important disorders considered are shown in Table I. Four of these

TABLE I.—PERCENTAGE FREQUENCY OF DISORDERS OF PREGNANCY AMONG MOTHERS OF DEFECTIVE CHILDREN

| | Excessive vomiting | Emotional shock | Falls and other accidents | Threatened abortion | Toxæmia | Rubella |
|---|---|---|---|---|---|---|
| Controls (742) .. .. | 5·0 | 0·3 | 0·0 | 1·1 | 5·1 | 0·0 |

| Spina bifida (309) .. .. | 6·5 | 1·3 | 1·3 | 1·9 | 3·9 | 0·0 |
| Pyloric stenosis (488) .. .. | 6·4 | 3·1 | 7·6 | 3·9 | 4·7 | 0·0 |
| Patent ductus arteriosus (150) | 4·7 | 4·7 | 6·0 | 4·0 | 7·3 | 2·0 |
| Congenital dislocation of the hip (167) .. .. .. | 9·0 | 0·6 | 4·8 | 3·0 | 7·2 | 0·0 |
| All malformations (1,419) .. | 7·2 | 2·2 | 4·3 | 3·3 | 5·1 | 0·2 |

No. of cases is given in brackets.

conditions (excessive vomiting, emotional shock, falls and accidents, and threatened abortion) appear to occur more frequently among mothers of malformed children than in the control group. There is some evidence, which cannot be given in detail, that the malformations considered here have very different ætiological features—anencephalus and spina bifida are laid down at an early stage of embryonic life; pyloric stenosis is dependent, at least in part, on factors in the post-natal environment; and some cases of patent ductus arteriosus and of congenital dislocation of the hip appear to be related to the conditions of birth. It would not be expected, therefore, that all these defects would be associated with

excessive vomiting in pregnancy, or with emotional shock, or falls, or threatened abortion. The fact that these episodes are recorded more often by mothers of malformed children is probably due to the mother's attempt to account for the defect, so that she recalls disorders of a trivial nature which the mother of a normal child would have no reason to remember.

This difficulty can be overcome by ignoring the control series and restricting the examination to a comparison between the different groups of malformations. Their diverse ætiology makes it unlikely that a disorder of pregnancy which was associated with one type would show a similar association with every kind of malformation. Mean frequencies based on the combined series of malformations are given in the bottom row of the table. For four disorders of pregnancy (excessive vomiting, emotional shock, threatened abortion, and toxæmia) the mean values are not exceeded by a significant amount by any of the malformations. The frequency of falls and accidents among mothers of children with pyloric stenosis appears to be significantly raised, but there are reasons for believing that this does not indicate a causal relationship. Histories of rubella were recorded only three times and all occurred in the patent ductus arteriosus group. Although the number is very small there is little doubt of a real association. But the great majority of cases of patent ductus appear to be due to some other factor. No other infectious disease has been recorded with sufficient frequency to suggest any causal relationship with any of the malformations studied.

It is concluded that very few of the malformations we have investigated can be accounted for by any remembered event in pregnancy. In attempting to explain this result we may consider the following possibilities:

(1) We may not have been asking the right questions, or we may have been disregarding information in the maternal history thought to be irrelevant, or the events in pregnancy of ætiological importance may be so trivial that they are not remembered. In these circumstances, a careful prospective enquiry should provide some information and we hope that we shall soon be able to report such a study.

(2) The second possibility is that human congenital malformations are determined entirely or almost entirely by inheritance and that environment plays little or no specific part in their causation. This seems to be unlikely for two reasons: it is very difficult to formulate acceptable hypotheses involving genes of full penetrance, and in most of the malformations we have studied we have found evidence of environmental influences. This evidence consists mainly of variations in incidence with the age and parity of the mother and with season, but more specific observations are available in the case of anencephalus, pyloric stenosis, patent ductus arteriosus, and congenital dislocation of the hip. Space does not permit a review of the evidence here: details may be found in the publications listed at the end of this paper. It is possible, of course, that variation of incidence with maternal age and parity and with season may reflect the action of environmental influences in removing malformed embryos from the uterus at an early stage of development. Nevertheless a review of all the evidence strongly suggests that the intrauterine environment plays some part in the ætiology of a number of congenital malformations.

(3) The most likely reason for our failure to relate most congenital malformations to events in pregnancy is that abnormalities in the intrauterine environment which cause malformations or are favourable to the continuation of development of defective embryos do not reveal themselves as overt maternal disease. It seems useless to speculate on the nature of these influences until more is known about the epidemiology of the various malformations.

**Dr. J. A. McCredie Smith** (Manchester):

In the past thirty years there have been a number of studies of perinatal pneumonia, i.e. diagnosed histologically in stillbirths and in infants dying in the first week of life. Its significance as a cause of perinatal death has not been fully appreciated because the clinical features are elusive and the naked-eye findings at autopsy scanty.

When post-mortem examination of infants dying in the perinatal period is routine, and when the lungs of these infants are examined microscopically, the incidence of pneumonia is found to be considerable. Kjessler (1955) in 361 perinatal deaths found 70 with pneumonia. Ahvenainen (1953) noted that 206 (54%) of 384 infants who died during the first week of life had histological evidence of pneumonia.

We have carried out a study of pneumonia as a cause of death in perinates and an attempt has been made to determine some of the factors that contribute to infection of the fœtus. The study is in two parts—a retrospective investigation which consists of contrasting the infants with pneumonia against those who showed no evidence of pneumonia. The second part is a clinical investigation into the exact part which infection played in causing perinatal death. This investigation was necessary because many workers have observed that the lesions found post mortem in stillbirths and in infants dying shortly after birth are usually multiple, and it is often difficult to determine which lesion is the principal cause of death and which contributory. So, the presence of pneumonia, which is the commonest evidence of infection, does not necessarily represent the significance of infection as a cause of death.

*Retrospective Study*

This comprised 90 perinatal deaths seen in the years 1950, 1952 and 1954. About 10% of stillborn infants showed evidence of pneumonia but pneumonia occurred in 25% of infants dying on the first day of life and in 30% of those dying on the second day. Thereafter it became of relatively less importance. Though pneumonia was more common in non-macerated stillborn infants, it frequently occurred in macerated infants. This indicates that infection is not just a terminal event but can sometimes occur before birth.

It is obvious then that assessment of the role played by pneumonia in causing death is very difficult.

Because this was a retrospective study much of the information that was required was not recorded on the notes. The only significant maternal finding was that prolonged rupture of the membranes (over forty-eight hours) occurred more frequently in the pneumonia series as compared with the control series.

The next factor to be examined was the placenta. Inflammation of the placenta can occur at several sites. Initial studies indicated that inflammation of the chorion or round the vessels of the fœtal surface was important. There was a highly significant correlation between inflammation of the fœtal surface of the placenta and the occurrence of pneumonia, and at the same time the fœtal vessels were frequently involved. These findings suggest that not only can a fœtus be infected by aspiration of infected liquor but that infection spreading via the blood stream is also very important.

*Prospective Study*

As our experience suggested that infection plays a considerable part in the causation of perinatal mortality and morbidity, an investigation was designed to determine the significance of infection as a cause of death.

Two groups of women who were either in labour or whose membranes had ruptured were selected from those admitted to hospital. The first group were all those thought to have an intrapartum infection, 137 in total. This group was further divided by strict alternation into 68 patients treated with antibiotics and 69 who received no antibiotics. The second group was a control group in whom no intrapartum infection was suspected. This consisted of every fifth patient admitted in labour into the hospital and numbered 99 in all. There are obvious shortcomings in the control group.

The diagnosis of intrapartum infection was based on two criteria: a maternal pyrexia of 98·6° F. or over, measured on a four-hourly temperature chart, or a fœtal tachycardia of 160 or over, maintained for ten minutes. The presence of either of these criteria was taken to indicate intrapartum infection. A full bacteriological and pathological examination was made in all cases.

For the purpose of the therapeutic trial alternate women admitted into the infected group were given combined antibiotics—intramuscular streptomycin 1 gram twice daily and oral oxytetracycline 500 mg. six-hourly—from the time the infection was diagnosed until the patient was delivered. A combination of two antibiotics was used because the organisms were unidentified on admission to the trial, and because the organisms were less likely to develop resistance.

*Results*

The treated and untreated infected groups were alike with respect to the relative frequency of maternal pyrexia and fœtal tachycardia, and in age, parity, social class and in the frequency of toxæmia, surgical interference and prolonged labour. However, they differed from each other, and from the uninfected control group, in their incidence of notifiable puerperal pyrexia and in perinatal mortality (Table I).

| Group | Total patients | Puerperal pyrexia | Fœtal deaths Total | Fœtal deaths With evidence of pneumonia |
|---|---|---|---|---|
| Infected—not treated.. | 68 | 18 (26%) | 10 (15%) | 5 |
| ,, —treated .. | 69 | 9 (13%) | 5 (7%) | 0 |
| Not infected (control) | 99 | 5 (5%) | 0 (—) | 0 |

Notifiable puerperal pyrexia was commonest in the infected untreated group, 18 cases out of 68, a morbidity rate of 26%. The treated group had half that rate, 9 cases out of 69, 13%, and the uninfected group least of all, 5 cases out of 99, 5%. The difference between the infected untreated group and the uninfected group was most unlikely to be fortuitous.

Fœtal death was commonest in the untreated infected group, 10 deaths out of 68 (fatality rate of 15%) of which 5 gave evidence of pneumonia. Among the 69 treated infected patients there were only 5 deaths (fatality rate of 7·2%), none with evidence of pneumonia. In the 99 uninfected controls there were no fœtal deaths at all. Most of the deaths, including all the pneumonias, in the infected untreated group were of infants whose mothers had over forty-eight hours infection, measured from the first sign until delivery. The difference in fatality rate between the infected untreated and the uninfected controls was highly significant, but the difference between the treated and untreated groups of infected patients was not formally significant ($p > 0{\cdot}05$) except among those with over forty-eight hours' duration of infection.

The pathogenic organisms associated with perinatal deaths were mainly *Escherichia coli*, *Streptococcus fæcalis*, non-hæmolytic streptococci, and rarely a hæmolytic streptococcus. 38% of presumed uninfected women had pathogenic organisms in the upper vagina, but only 2% of placental blood cultures were positive. In the untreated infected group the corresponding percentages were 73%, with 13% of positive placental blood cultures. Furthermore in certain instances in which there was a fatal pneumonia in the infants the vaginal swab, the placental blood, and the lung culture all showed the same organisms.

The mechanism of fœtal infection may be explained as follows: Bacteria commonly found in the vagina, or introduced by the attendant, enter the uterus and infect the decidua. In some women, infection spreads to the placenta or membranes or both. Often the infection gets no farther, but sometimes it spreads to the fœtus by the fœtal blood stream or by aspiration of infected liquor. The effect of perinatal infection is usually relatively slight on the mother but can be disastrous for the infant, because organisms of relatively low virulence for the mother have a much greater effect on the infant, who has little or no immunity. Such a concept is consistent with the higher frequency of puerperal pyrexia in infected cases than in controls.

The bacteriological studies of the vaginal flora suggest that antibiotic therapy reduces the incidence of potential pathogens. The effect on the fœtus may therefore be twofold: antibiotic therapy may eliminate some or even all of the organisms in the vagina so that infection of the fœtus is prevented; or, if the infection is established in the fœtus, it may control it and facilitate recovery. Furthermore, the combination of antibiotics used in this investigation tends to reduce the possible development of resistant strains of organisms.

## DISCUSSION ON ORGANIZATION FOR IMMEDIATE POST-OPERATIVE RECOVERY PERIOD

**Dr. Russell M. Davies** (East Grinstead):

A patient leaves the operating theatre with three handicaps to his return to health.

(1) The basic pathology, namely the disease process.
(2) The blood loss and trauma of surgery.
(3) The residuum of anæsthesia.

It is at this time that the need for skilled and continuous care is greatest. This period may be short or long. The after-care needed may be complicated, requiring the intervention of many medical specialists; or it may be simple. Whichever it may be, vigilant nursing will always be required for the appropriate period. In seeking this degree of care it is difficult to concentrate all the required skills in the right place at the right time. Where several such patients are scattered around the hospital dispersal will be wasteful of both doctors and nurses. This will always be true whatever the size of the hospital. Where the hospital is anything but a small one, surely it is logical to have a single place where all these desirable skills may be applied to the patient, and I would submit that the best place would be a recovery ward.

The provision of such a focal point is becoming more and more urgent. Skilled nurses are increasingly difficult to obtain. This difficulty will be felt first, and in fact is already being felt, in the peripheral non-teaching hospital; but in time it is probable that it will be felt too in the teaching hospital and this shortage of trained nurses was one of the most potent factors in the U.S.A. in spreading the institution of the recovery ward. In 1954 a questionnaire was sent out by the American Hospitals Association (Higgins, 1954) asking the hospitals whether they had recovery ward facilities of any sort and the following are some of the figures which were obtained. Of the smaller hospitals, 2% had recovery ward facilities; of the medium sized hospitals, 42% had recovery wards; of the largest hospitals, 55% had recovery ward facilities. The totals showed that out of 3,000 hospitals answering the questionnaire, 1,300 had recovery wards of one sort or another and the bigger the hospital the more likely was it to have a recovery ward. Since 1954 it is almost certain that these numbers have been increased. In this country, too, I am sure we will see the increasing adoption of the recovery ward as the best means of using the nursing skills which will be decreasingly available to us.

The recovery ward may be nothing more than a simple single room for the accommodation of selected patients as they leave the operating theatre, or it may be a large open space fitted with oxygen and suction. Alternatively it may be a large many-roomed unit or it may combine both arrangements, with a relatively large area in which the truly transient patient may be nursed, together with individual rooms to accommodate the seriously ill and longer stay patient. I think it is fair to say that there is no one ideal plan for a recovery ward, which must be designed to serve the surgical and geographical needs of the hospital so that it will be able to nurse the greatest possible number of patients. Where the hospital is a scattered unit the ward may be a large one, where the hospital is a compact unit the recovery ward may be a smaller one; but whatever the design I feel that certain principles must be observed in establishing such a ward. In February 1946 a recovery ward of 10 rooms was opened at the Queen Victoria Hospital, East Grinstead. During this period of slightly under twelve years, the ward has nursed approximately 33,000 patients, and out of this experience the following principles have come.

(1) *The ward should be staffed for twenty-four hours a day.* It is in fact easier, administratively, to staff a ward round the clock than to open it from 8 a.m. to 8 p.m. Furthermore, twenty-four-hour staffing will mean that the ward is always available for those who frequently need it most—the surgical emergencies. In the case of our own ward, normal ward staffing arrangements are followed throughout the day and night. There is a charge-nurse supervising the ward with the rank and pay of a departmental sister. The nursing administration comes directly under the Matron of the hospital and not under any other departmental sister. The sole duty of the nursing staff is to care for the patient in the post-operative period and thus develop interests and skills more single-mindedly than if their appointment was a joint one to one or two units in the hospital.

(2) *All patients who have had general anæsthesia should pass through the ward.* Any other procedure involves guessing which patients will give trouble in the post-operative period and which will not. Inevitably, one day, one will guess wrongly, maybe with a fatal result.

(3) *The standard of nursing skill in the ward must be equal to the best in the hospital.* Some nurses make better theatre nurses than others, and some better surgical ward sisters than others. Similarly there is no question but that some nurses make better recovery ward nurses than others. The good recovery ward nurse is no more skilled than any other able nurse. It just happens that her aptitude is different. This skill must be sought for and employed. Above all, such a nurse must have the ability to observe a patient from moment to moment and act unerringly, frequently at speed, upon the results of these observations.

(4) *The nursing staff should never be moved from the ward as a group.* Nursing training is most easily and effectively carried out at the bedside. It is necessary to have in the ward not only a constant level of ability and knowledge, but also a continuous informal training programme. This can best be done by making single staff changes rather than block changes so that an even level of knowledge and skill is maintained in the ward. Furthermore an attempt should be made to retain at least one of the staff for a prolonged period at least of months to act as an efficient deputy for the ward sister when she is off-duty. At the present time at the Queen Victoria Hospital, East Grinstead, for our recovery ward of 10 rooms the staff is as follows: By day—one male nurse in charge with the status of a sister, four State-registered staff nurses who are moved from the ward at intervals varying from one year down to six weeks, and, finally, two ward orderlies. At night the staff consists of one State-registered nurse and one nursing aid. Whenever the number of night emergencies admitted to the ward rises, it is accepted by the nursing administration of the hospital that this number of night staff should be augmented, even at the expense of depleting the night staff elsewhere in the hospital.

(5) *The level of record keeping must be high and all ward procedures must be adhered to as rigorously as in other wards.* Record keeping must be accurate and detailed because it must be realized that the introduction of a recovery ward forges another link in the chain of patient care. Information must be received and understood when the patient arrives from the operating theatre. This, with the addition of the recovery ward information, must be accurately transmitted when the patient returns to his own ward. This link must be unbreakable. The records will be of two types: firstly, those maintained for ward purposes—including details of the reception and discharge of the patient, treatment records, drug records, &c.; and secondly, the patient's records. These will include all details of the surgical procedure, post-operative incidents, or the lack of them, and all treatment while the patient is in the recovery ward, and these must go with the patient to his own ward. We have found that this is most readily done by the sister making the appropriate entries as an integral part of the patient's case notes. These must be completed before the patient leaves the recovery ward for his own ward.

(6) *The recovery ward must be close to the operating theatre.* It has been our practice that the sister of the recovery ward or her deputy goes to the operating theatre to receive the patient from the surgeon and anæsthetist. The patient is placed in the recovery ward bed at the operating table side and at the same time instructions are given on the immediate post-operative care required. When the ward is close to the operating theatre it is also possible for the surgeon and anæsthetist to make frequent visits to see their patient, and indeed it soon becomes a habit to do so. Finally, the distance which the patient will have to travel will be a short one, and the report by Pask (1955) emphasizes the importance of this point.

(7) *The recovery ward must be adequately equipped with resuscitative equipment.* Piped suction and oxygen are at the very least a convenience. All the necessary solutions for infusion should be readily available.

(8) *Medical care must be immediately available in the ward at all times.* It has been our practice to regard the senior house officer in anæsthetics as having the same relationship to the recovery ward as has the house physician or house surgeon to *his* wards. It is his responsibility to call the appropriate consultant in the event of any crisis arising. He will visit the ward from time to time during the day and also before going to bed at night. When he is off-duty alternative cover is provided by the other junior staff. In addition, at all times throughout the day and night a senior member of the anæsthetic staff is available for consultation and call. Finally, the nursing staff must be kept aware of the whereabouts of the doctors to whom reference may be made.

(9) *There should be facilities for the retention of a patient in the recovery ward for as long as the facilities of the ward will benefit the patient.* In our experience the stay of the patient in the ward has varied from 20 minutes to 13 days. 95% of the patients stay in the ward twenty-four hours or less, but again the practice will obviously vary both with the methods adopted in different hospitals and also with the type of surgery that is done. For example, in the Research and Educational Hospital of the University of Illinois in Chicago, 10% of all patients stay in the recovery ward for forty-eight hours or more. On the other hand in St. Mary's Hospital, Rochester, Minnesota, the recovery ward (or Post-Anesthesia Room, as it is called) is open only from 8 a.m. to 5 p.m. (Mayo Clinic Section of Anesthesiology, 1945), no patients being admitted after the latter hour.

## Discussion

Publications from this country and America leave no doubt of the life-saving function of the recovery ward. At different times articles have appeared analysing the post-operative care of something like 100,000 patients, and in all instances the opinion has been given that as a result of the institution of these wards lives were saved. In re-reading Pask's article of 1955 one cannot but feel that many of the deaths which he recorded would not have happened had adequate and readily available nursing care been at hand. He gives the opinion that death in 58 cases appeared to be due to an insufficiency of post-operative care. He says "in 49 the fatal process began as a respiratory disturbance—either obstructed respiration or inadequate respiratory movements; in 20 cases the patient was found dead, and in 8 of those the patient was found dead on arrival in the ward from the operating room, and in 7 the journey was a long one; in 10 cases the inhalation of vomitus or blood could clearly be identified as the critical event; there were 19 cases following the use of a relaxant, when respiratory insufficiency (other than obstruction) was present post-operatively and again the attendant was an inexperienced one". Our own experiences would confirm all these impressions.

Among the 33,000 patients for whom we have cared following surgery there have been many anxious moments. These moments have occurred often enough for us to feel that any attempt to prophesy which patient would encounter post-operative difficulties is fruitless. Of this number of patients a total of 11 have died, and of these 11 we believe that *one* would be classed as avoidable by the investigators of the Association of Anæsthetists. This gives an overall mortality rate of approximately 1/3,000, compared with a rate of 1/1,300 before the ward was opened.

Finally, a recovery ward has two advantages and one disadvantage. It saves lives and it saves nurses; but it costs money.

**Mr. J. R. Belcher** (London):

The immediate post-operative recovery period should cover at least forty-eight hours. By no means all the emergencies occur within the first six hours and the small hours of the morning appear to be particularly dangerous.

Secondly it is essential that there should be some sort of transition stage between the end of an operation and the return of a patient to an ordinary ward. Clearly the details of this transition must vary widely from hospital to hospital, for both the type of work and the topography must have a dominant influence upon the arrangements.

These opinions have been confirmed by my experience at the London Chest Hospital, where we have what I consider to be an almost ideal recovery ward arrangement. However, relatively few very major cases are operated upon each week, in contrast to the situation at East Grinstead.

Some of the arguments in favour of the "recovery ward" principle are as follows. It is possible to concentrate an adequate number of experienced and competent staff there: it is possible to have readily available all the apparatus which may be required in an emergency: bronchoscopes, suckers, transfusion sets, mechanical respirators, equipment for cardiac resuscitation, &c., and lastly nocturnal disturbance of convalescent patients can be avoided by this segregation.

I do not agree with Dr. Davies that all patients should pass through such a ward, but that only major and complicated cases should do so. This is not, in fact, a view widely divergent from his, for I believe that no patient should leave the theatre suite until he is "round" and breathing satisfactorily. The corridor outside the theatre may well thus be regarded as a primitive form of "recovery ward". I also believe that patients who have been "cooled" should not leave the theatre, let alone the suite, until their temperature has reached at least 35° C. and until they are showing signs of spontaneous respiration. The anæsthetist's attention should not be divided at this stage.

I believe that a recovery ward must have a whole-time staff and that the "nine till five" system may be dangerous. At the London Chest Hospital the patients are transferred to the ward before their operation and kept there for at least forty-eight hours after it. We find that eight beds are sufficient to cope with our average weekly list of 10 cases.

Ideally the ward must be near the theatre, and on the same floor. It can thus be easily accessible should anything go wrong in the middle of a list. It must be well lit, but fluorescent lighting should be avoided as it makes cyanosis difficult to recognize.

I shall now go on to define the hazards which a recovery ward is designed to lessen.

Perhaps the commonest cause for alarm is respiratory obstruction. This may be due to a variety of causes, most of which are easily corrected, but should they occur in the hands of an inexperienced nurse during the transit between a theatre and a distant ward they may be lethal. The second hazard is anoxia which may also be due to a variety of causes, such as respiratory depression and blocked tubes. Again these may be easily dealt with in a well-equipped ward, but not in a lift. The same comments apply to the third hazard—carbon dioxide retention. Major hæmorrhage is the fourth catastrophe which has to be prepared for. The time saved in a ward where blood and apparatus are readily available may be life-saving. Lastly, cardiac arrest: this is happily uncommon in Britain. Nevertheless it does occur, but as it is almost always fundamentally due to anoxia, it is my conviction that it may often be avoided by timely bronchoscopy in those patients whose major bronchi have become obstructed by blood or vomit.

Should arrest occur, thoracotomy and massage must be rapidly undertaken. The procedure is easy, but the decision to open the chest is difficult; for this reason it is not often successful. It is certain, however, that apparatus and, more important, trained staff should be immediately available: hence the necessity of a recovery ward near the theatre.

These are some of the disasters which have to be provided for. My last point is concerned with who should be responsible for the treatment of these complications when they occur. There is a considerable risk of over-treatment of patients at this stage, and one man should therefore have overall responsibility. Most of the hazards are to a greater or less extent related to the anæsthesia, and the anæsthetist should be reponsible for their treatment. As a corollary, I think that all anæsthetists should have some of their training in a chest unit where bronchoscopy is common and cardiac arrest by no means unknown. In a general hospital it is clearly impossible for all the surgical registrars and house officers to become familiar with the techniques which may be required in an emergency, and therefore I think that the limited experience available should be acquired by one man: the senior resident anæsthetist.

**Dr. T. B. Boulton** mentioned that a report on the working of their post-operative observation ward at Southend-on-Sea was published by Jolly and Lee in January 1957 (*Anæsthesia*, **12**, 49). All concerned were now agreed that the benefits of having a post-operative observation ward far outweighed the disadvantages, and that this was especially true in any hospital where there was a shortage of nursing staff.

The danger of the recovery room becoming a kind of medical "No Man's Land" was a real one, but this had been overcome by careful co-operation between surgeon, anæsthetist, and physician. It was certainly essential that a single registrar should have responsibility for the post-operative observation ward. Like Dr. Davies, they had found that this duty was most easily performed by the senior of the anæsthetic registrars.

Three distinct types of case passed through their recovery room:

Firstly: Trolley cases, relatively minor surgical procedures on fit individuals who remain only for a short while to recover completely from their anæsthetic.

Secondly: More major surgical procedures who remain in their beds for twelve to twenty-four hours before being returned to the wards.

Thirdly: Very ill patients who require special nursing for several days.

Perhaps the last group did not strictly belong to the province of the post-operative ward, but the fact that surgeons often preferred to leave such patients in the ward bore ample testimony to the quality of the specialized nursing skill available.

During a recent visit to the United States where the nursing shortage is acute, it was certainly evident that the recovery ward had become an essential part of the surgical set-up. In some centres, such as in the hospitals associated with the Mayo Clinic, specialized techniques such as hypothermia and cardiopulmonary by-pass had caused the development of specialized long-term recovery units. As cardiac operations became more complicated and radical, it might even be necessary to provide sleeping accommodation in the Unit for the use of medical staff so that they might be close at hand during the early post-operative period.

Besides the benefits of close supervision of post-operative patients, the post-operative observation ward brought facilities for simple clinical research within the reach of the ordinary working anæsthetist. Ward sisters and nurses in general wards could not be expected to help in observing and recording special data, but in the post-operative ward they could and did help; indeed recording such data should be part of the routine.

They did not agree with Mr. Belcher that it was a good thing for patients to be admitted to the post-operative ward prior to operation. One individual, who was sometimes forgotten when considering the pros and cons of recovery rooms, was the patient low on the operating list who, but for the recovery room, was forced to see his fellow patient returning from the theatre festooned with all the paraphernalia of modern surgery—drips, drains and the like. Occasionally, even in these days, the patient vomited or was shocked or delirious. How much better that the pre-operative patient should be spared the mental trauma of seeing his ward-mates in the early post-operative period.

With the modern methods of rapid induction at their disposal, one might almost say that a post-operative recovery ward was more essential than a pre-operative anæsthetic room.

**Dr. A. C. Fraser** said that there had been a recovery room at Lincoln County Hospital for five years. It was adjacent to the theatres, worked from 9 a.m. to 5 p.m. and patients stayed about an hour. Eight beds were sufficient for two busy theatres. They had always managed to find a part-time sister to staff the room and the theatre provided extra help when needed. To make up for some loss of experience groups of student nurses came to the theatre for special instruction in post-operative care and an anæsthetic nurse was appointed each month to help the anæsthetists.

**Dr. Eric Gardner** pointed out that a fully equipped recovery room with its specially trained staff under the anæsthetist's supervision was the ideal place for the treatment of certain medical emergencies, such as barbiturate poisoning, tetanus and other cases of respiratory failure.

**Dr. G. F. Rawdon Smith** thought that one of the main difficulties in the provision of such a ward was the shortage of hospital beds throughout the country and that the use of one ward for both pre- and post-operative cases had practical objections. He was also afraid of still another specialty being created in an already over-burdened profession.

**Dr. J. Alfred Lee** felt that the success of a post-operative observation ward depended largely on the efficiency and devotion to duty of the nursing staff. He made the suggestion that the name of such units should be Post-operative Observation Wards. The unit was primarily for careful observation and as such it fulfilled a most useful function.

**Dr. Laurence Mountford** said that while it was true that most cases of cardiac arrest were anoxic in origin, and bronchoscopy might well remove the cause of anoxia, bronchoscopy in itself could readily be a cause of cardiac arrest, especially in the presence of poor respiration, when suction would reduce the alveolar oxygen to disastrous levels. Bronchoscopy could be safely carried out only in the presence of two conditions: full respiration and a blood pressure within near-normal limits.

If patients were returned to the ward in an adequate state of recovery, the physiotherapist could immediately begin the treatment designed to prevent atelectasis, a very important part of post-operative recovery.

If the responsibility for post-operative care was to lie with the S.H.O. in anæsthetics, then it was most important that the R.S.O. should have continuous access to his patient in order not to miss a most vital part of his training.

**Mr. St. John Birt** said that, as a surgeon concerned in planning a new theatre block for a small provincial hospital, he was particularly interested in the number of beds which should be made available in a recovery room in relation to the amount of operating carried out in the theatre, and that as both the opening speakers came from large centres doing specialist work, it would be helpful to have the views of those carrying out more general work.

As to whether the surgeons or the anæsthetists should be in immediate control of post-operative recovery, he felt that surgeons were now in the same position in relation to the treatment of shock as they had been in relation to the giving of anæsthetics twenty years ago. At that time the surgeon felt responsible for the anæsthetic and was not averse to giving advice as to how it was to be administered. To-day he would not consider tendering such advice. However, he still gave advice about the treatment of shock, but as in most cases anæsthetists knew a great deal more about this treatment than surgeons, Mr. Birt considered it was time that the surgeon handed over the treatment of the patient's general condition in the immediate post-operative period to the anæsthetist.

**Professor E. A. Pask** asked whether patients whose operations were associated with special metabolic problems (e.g. hypophysectomy) should be taken to recovery wards or should return immediately to the care of the specialist teams. He wondered also whether a patient who had been ill for a long time and deeply trusted the nurses who cared for him, might not be distressed to recover consciousness amongst strangers.

Professor Pask spoke of experience in a hospital with widely separated single operating-rooms, not always very logically arranged in relation to their wards. In these circumstances, although a central recovery ward would be economical of nursing staff, many of the post-operative patients would be far from the surgeons and anæsthetists.

**Mr. Belcher** in reply also stressed that the recovery ward should be as near to the theatre as possible, and that no standard plan is possible as hospitals differ so much in their lay-out and in the type of work carried out.

**Dr. Davies** in reply to Professor Pask gave as his opinion that where the choice lay between concentration of recovery ward facilities and proximity to the operating theatres, the latter would be the choice which he would support. [Mr. J. R. Belcher later agreed with this view.] In Dr. Davies' opinion even where patients have gained confidence in and come to depend upon their ward staff, provided that the ideas behind the recovery ward were explained before operation, they appreciated the period of quietude and seclusion in the specialized surroundings of the recovery ward in the immediate post-operative period.

With regard to such cases as hypophysectomy, he felt that each unit would no doubt make arrangements best suited to local circumstances, but he felt that the facilities of the recovery ward should not be completely disregarded.

In reply to questions concerning the ratio of recovery ward beds to operating theatres he mentioned several methods of calculation which had been suggested in the past. (*a*) Two beds per operating table. (*b*) A number of beds equal to the maximum possible operating list. (*c*) A number of beds equal to the average number of cases per day.

At East Grinstead the latter scheme had been adopted, and they had found that ten beds could handle 3,000 cases a year satisfactorily, but they were somewhat cramped when the number rose to 3,600.

In reply to a further question Dr. Davies stated that the House Surgeon to any case was urged to visit his cases in the recovery ward as often as he wished, in order to give the appropriate post-operative surgical care. There was not, and could not be, any sense of competition between surgical and anæsthetic departments in this ward. The work of the two was complementary, and resulted in no loss to the post-graduate training of the surgeon.

Finally, in reply to Dr. J. Alfred Lee, Dr. Davies pleaded that the name," recovery ward", should be retained in spite of alternative suggestions which have been made from time to time. It was a term which was easily understood, together with its implications, by the patient.

## The Ætiology of Polyneuritis

By A. M. G. CAMPBELL, D.M., F.R.C.P.

*Bristol*

I PROPOSE to consider only the ætiology of so-called infective polyneuritis or the Landry-Guillain-Barré syndrome.

Since the paper of Haymaker and Kernohan (1949) it has generally been accepted that the cases described by Landry (1859) and those by Guillain *et al.* (1916) are the same, the only difference being that Landry emphasized a brief, rapidly spreading, ascending paralysis with minimum sensory disturbance, whilst Guillain emphasized particularly a rise in the protein of the cerebrospinal fluid as being characteristic of this disorder. It is probable that most of Landry's cases were similar to those of Guillain but he was unable to examine their spinal fluids.

On the other hand it is undoubtedly true that some of Landry's cases may not have been similar and as Symonds (1949) has pointed out there are cases resembling those described by Landry which may arise from a biochemical lesion which has been unsuspected and may, as Symonds stated in this paper, be due to potassium poisoning and secondary to uræmia and renal disease. These, however, must be rare and the majority of cases are probably infective polyneuritis. Haymaker and Kernohan (1949) also drew attention to the fact that the protein in the cerebrospinal fluid is not always raised at the start of the illness but rises to a peak over the ensuing months and only begins to fall when the paralysis starts to improve. He also emphasized in his large series of cases that about 10% have a small cellular rise in the spinal fluid and not all cases show complete absence of cells.

Recent work has tended to emphasize that the Landry-Guillain-Barré syndrome is a non-specific reaction to several infective agents and is due possibly to an abnormal antigen-antibody response. Miller (1955) has also claimed that it follows specific fevers such as measles, but Tyler (1957) (in a recent review of the neurological complications of measles in the United States) has denied this and found no case of infective polyneuritis associated with measles, nor in any of the cases that I have seen has any specific fever preceded the polyneuritis.

What has been striking in examining the literature is what Haymaker and Kernohan (1949) suggested, that sometimes there is an association with an illness resembling glandular fever before the onset of the polyneuritis and that some of the cases at least show a lymphocytosis before the onset of the illness. The second point which emerges very clearly from examining my own cases and the literature is that in about 60% of cases there is a respiratory infection with cough, sore throat and pyrexia before the onset of the polyneuritis and in another 10% to 20% of cases the onset is heralded by an attack of diarrhœa. It is interesting to compare this with the onset of poliomyelitis which also can be preceded by a respiratory infection and sore throat or an enteric infection. In Haymaker's series two cases followed injections of anti-tetanic serum. Again there is some resemblance to poliomyelitis in the precipitation of this disease by an injection.

This condition does not resemble the allergic encephalomyelitis following specific fevers such as measles and chickenpox, but does, in point of fact, resemble what previous workers have suggested, a virus infection of unknown ætiology and there is some evidence from previous experimental work that this in fact may be so.

Many writers have expressed the opinion that human cases of infective polyneuritis were due to a virus infection. Leschke (1914) injected material from the spinal cord of a case of ascending paralysis in a 16-year-old girl into a monkey by both intracerebral and intraperitoneal routes and on the ninth day the monkey became paralysed and died.

Negative experiments were carried out by Lassen *et al.* (1943) who did not use monkeys but chiefly mice, rabbits and ferrets. Sabin and Aring (1941) also failed to convey the disease to mice, guinea-pigs and on one occasion a monkey. The most important work in this field, so far, has been that of Pappenheimer *et al.* (1951). They sent the fæces of a child

aged 4 years with progressive motor paralysis, to test for the virus of poliomyelitis by injecting material into monkeys. This produced lesions which were not those of poliomyelitis but severe degenerative inflammatory lesions of the spinal roots closely resembling the Landry-Guillain-Barré syndrome. They injected six monkeys intracerebrally and at post-mortem three of these animals showed neuronal degeneration of the spinal roots and peripheral nerves with or without marked lymphocytic infiltration. Further passage carried out by injection of spinal cord suspension of these animals was followed by the development of similar lesions in two of the six animals injected. Thus, five monkeys showed positive symptoms and pathological changes similar to infective polyneuritis, and in two others minor changes were found.

An attempt to transmit the disease to mice failed. Nor could further passage be established and no definite virus was isolated, but the experiment is of considerable importance as it was carried out with very strict control and in the second experiment material was kept for two years and this coupled with antibiotics was injected into the second group of monkeys thus excluding the possibility of an accidental virus infection of the monkeys themselves.

Many of the experiments that have failed to transmit this disease, may have failed because the virus was only pathogenic to monkeys and not to ferrets, mice, guinea-pigs and smaller animals which have been used. A search through the literature fails to reveal that any attempt to transmit the infection to a cat has ever been made.

The present investigation arose as a result of the speaker seeing a case of this disease three and a half years ago in which the story was that the patient's cat became ill with a respiratory infection called "cat influenza". Within a few days the patient's wife caught an influenza-like illness and two days later the patient became ill with a similar illness with respiratory symptoms followed within seven days by the onset of severe motor paralysis. This patient had a prolonged illness of the Landry-Guillain-Barré type, his proteins reaching 400 mg.% and is still left with some residual paralysis, the whole illness taking approximately nine months. His cat recovered and is still living.

Since seeing this patient 5 other personal cases have been seen in which the onset of the disease was directly related to an illness of the patient's cat. In one case the cat died and the diagnosis made by the veterinary surgeon was feline enteritis. In another case the cat had been diagnosed as cat influenza and in the other three cases the cat had had no veterinary attention and had recovered spontaneously after about two weeks' illness. When questioned, the patients were somewhat uncertain about the symptoms shown by the cat, but in two cases there was definite diarrhœa.

An analysis of all the cases of infective polyneuritis seen by myself in the last three years showed that in all there were 12 cases which all satisfied the criteria on clinical grounds. All had raised protein in the cerebrospinal fluid. Out of these 12 cases, 2 died, 1 on the first day of the illness of respiratory failure and 1 during the period of recovery, after having been in an iron lung, had a sudden pulmonary embolism and died on the twenty-first day of the illness.

10 cases have started with a respiratory illness with cough, sore throat and influenza-like symptoms. 2 started with diarrhœa which preceded the polyneuritis by one week and three days respectively. 5 cases had not had contact with a sick animal but had cats in the house at the time of the onset of the illness and one man, the patient who died after twenty-four hours' illness, had the cat to sleep with him in his bed, although it must be admitted that the cat had not apparently had any symptoms of illness.

These results were sufficiently striking to inquire whether other people have had similar experience. Dr. T. G. Reah of Harrogate reported a similar case who developed an infective polyneuritis about a month after her kitten had had what was probably feline enteritis. She herself attributed the illness, oddly enough, to contact with this sick cat which she had nursed throughout its illness. The more interesting letter was received from Dorset about 2 patients of Dr. E. B. Jarrett's. The first was a farm worker aged 48 who developed a picture resembling very closely that of infective polyneuritis and was admitted to hospital in Dorchester where he made an uneventful recovery. It must be added that although he had had syphilis in the past and had a positive Wassermann reaction in his cerebrospinal fluid and blood, Dr. Jarrett was of the opinion that the picture was not that of neurosyphilis but a genuine polyneuritis and there were no cells in his cerebrospinal fluid, his protein being well over 300 mg.%. This patient's cat was sent to a lady forty miles away to be looked after while its owner was ill. After a month it sickened and died of feline enteritis and this lady aged 65, a school teacher, was admitted with an acute infective polyneuritis and an attack of diarrhœa from which she died. She had progressive weakness of all limbs of very rapid onset and after being placed in a respirator she died ten days after the first symptoms. Cerebrospinal protein examination was carried out and was 160 mg.%; cells were 3.

If, as is probable, these were both cases of infective polyneuritis there was this very interesting story of a link between these two cases of a somewhat rare disease by the same

cat which eventually died from what the veterinary surgeon considers to be definite feline enteritis.

Subsequent to this, I have heard of 2 other cases linked with an illness in a cat.

On clinical grounds, therefore, there appears to be quite strong evidence, which is difficult to imagine as pure coincidence, that this syndrome can at least occasionally be linked with an illness of cats.

The help of Messrs. Burroughs Wellcome was enlisted to investigate this problem and I must pay tribute to the help I have received from Mr. A. B. MacIntyre at their Veterinary Research Laboratories.

There are two main infectious diseases of cats, the first is an influenza-like illness infecting the lungs and is due to a large virus of the same family as that which gives rise to psittacosis and lymphogranuloma inguinale. After consultation with Mr. MacIntyre and after negative Frei tests on our patients he considered that the evidence that this was the disease responsible was not great and he thought it far more likely that a much more serious infective condition of cats, feline enteritis, might be responsible for the illness in the cats and human beings and it is on this assumption that work has proceeded.

Feline enteritis in cats has a mortality of about 20% and is highly infectious from animal to animal, chiefly affecting young cats and kittens, and probably 70% of all cats at some time or another are infected. The disease is characterized in cats by a general inflammatory reaction of the gut, intense diarrhœa, agranulocytosis and enlargement of the lymph glands.

Messrs. Burroughs Wellcome have developed a vaccine against this virus which has helped to control this infection.

They have carried out complement-fixation reactions on the serum of my patients who have suffered from infective polyneuritis, using as antigen cats' tissue (spleen and lung) infected with feline enteritis virus and also two tissue cultures similarly infected. Using a limited number of laboratory workers as controls the results, as far as they have gone, have suggested that there is a distinct difference between the patients' bloods and those of the controls and suggest that it may be possible to get pathological confirmation of the clinical association of infective polyneuritis with cats.

## Some Aspects of Referred Pain [*Abstract*]

By C. W. M. WHITTY, D.M., M.R.C.P.

*Oxford*

KELLGREN and Lewis in 1939 described referred pain of roughly segmental distribution from 6% saline injections into the interspinous ligaments. This work has been applied in the investigation and treatment of patients with persistent spontaneous pain and with known lesions of the pain pathways. The possibilities of referred segmental analgesia from similar injections of procaine have also been explored.

In the normal subject 6% saline will produce local stinging pain around the site of injection; it may also produce deep aching pain, skin hyperalgesia and palpable muscle spasm often bilateral and all within the same somatomeral segment as the injection. These effects can be rapidly reduced by the injection of 2% procaine into the site of saline injection.

In patients with spontaneous pain from post-herpetic neuralgia or painful scars, 6% saline in the appropriate interspinous ligament will aggravate the pain and hyperalgesia; 2% procaine if given two to five minutes later into the same site will abolish this aggravation and reduce the level of spontaneous pain, sometimes completely abolishing it. If procaine is given alone this also will reduce spontaneous pain but the effect is less marked

and less long-lasting than that of saline and procaine. When a series of such combin injections is given there may be permanent reduction and very occasionally permane abolition of spontaneous pain. In a patient with post-herpetic pain in the D3 and segments on the left, and angina of effort referred to the left arm, it was found that int costal nerve blocks of the herpetic area and procaine to the D3 and D4 interspinous lig ments each gave relief both of the herpetic pain and also of the angina of effort. Sali aggravated the post-herpetic pain but reduced the effort angina. Combined saline a procaine was more effective in relieving the herpetic pain and repeated injections ga permanent improvement.

In patients with spinothalamic tract lesions referred pain from mid-line saline injectio occurred only on the side with intact spinothalamic pathways. Referred sensation do occur to the other side, but it is a non-painful tingling. Bilateral unpleasant referre sensation, described subjectively as painful, was, however, noted in one such case: bu it was obtained only from the mid-dorsal segments and was unusually diffuse and referre deeply as "a feeling of being winded".

In one patient with a slight sensory level to both spinothalamic and posterior colum sense saline produced the expected segmental referred deep aching and muscle spasm, bu there was also a delayed severe skin hyperalgesia referred specifically to the upper limi of the clinical sensory level, seven or eight segments above the one injected.

It is emphasized that the referred effects of saline and procaine are inconstant. With apparently the same technique they may vary in the same patient on different occasions. In other patients they may not occur at all. Nevertheless they have potential therapeutic applications.

It is concluded that these observations lend support to the view of a sensory neurone pool in the spinal cord in which both summation and competition for a final common pathway may occur.

## Late Infantile Metachromatic Leucodystrophy

By MICHAEL JEFFERSON, D.M., M.R.C.P.
*Birmingham*

DIFFUSE cerebral sclerosis is a complex subject which has recently been well reviewed by Poser and van Bogaert (1956). It comprises a spectrum of diseases which have in common a general similarity of clinical and pathological outline, but they differ widely in detail, in their age of onset, time-span, inheritance or otherwise, and their microscopical anatomy, and they must differ too in their ætiology, though little enough is known at present of the cause of any of them. To some extent their classification is debatable, but broadly speaking they fall into three main categories. Firstly there is the group of conditions of which Schilder's disease is the prototype, secondly there is the class of subacute leuco-encephalitis and its analogues, and thirdly, there are the leucodystrophies, several types of which have been described whose affinities and distinctions are still not properly known.

### SYMPTOMATOLOGY

It is with the features of one form of the latter, namely late infantile metachromatic leucodystrophy that I want to deal. Examples of this malady have been described by several writers in the last twenty-five years, notably Greenfield (1933), Brandberg and Sjövall (1940), Brain and Greenfield (1950), Leslie (1952), Bertrand *et al.* (1954)[1] and Peiffer and von Hirsch (1955), and I have had recent personal experience of one case. In all of these, numbering 11 together, the correct diagnosis was only made after autopsy, but it ought not to be impossible to recognize (or at least suspect) the answer during life, if only the existence of the disease were more widely known, and the aim of this short paper is to draw attention to it as an entity.

Its semeiological pattern is a fairly constant one. The age of onset is commonly around 20 months, and the duration from first symptoms to death about 15 months. There is no evidence of sex predilection, nor much to suggest a familial tendency, but the data on the latter point are not fully satisfactory, since a majority of case reports have related to children without sibs. From the symptomatic point of view, the onset is most often with vague

[1]The case described by these writers was originally stated to be non-metachromatic, but metachromasia was found on re-examination by Diezel (1957).

fretfulness and slight disorder of gait, so that the child is no longer so confident on its feet as before. Insidiously over the course of a few months, the power to walk, or even to stand, is completely lost, and the upper limbs, neck and trunk muscles become considerably weakened as well, so that use of the arms, sitting without support, or even holding the head up, is difficult or impossible. At about this stage, as in one of Brain and Greenfield's cases, in my own, and perhaps in Leslie's case too, there may be general hypotonicity along with the loss of muscular strength, so that the child's appearance may call to mind some form of myopathy. This phase, however, may not be present, and in any event is transitory, soon passing into stiffness of the limbs, with extended legs and feet in equinovarus and the arms flexed. The tendon reflexes as a rule are by now unobtainable and the plantar reflexes upgoing. Sudden and frequent accessions of muscle spasm become noticeable, which exaggerate pre-existing hypertonus of the limbs, and produce bodily attitudes resembling experimental decerebrate rigidity. They are apt to be induced by any external stimulus or occur spontaneously, are usually accompanied by crying, and may last many minutes at a time. Meanwhile cranial nerve signs have also developed, in the form of ptosis or nystagmus or both. The appearance of the latter can vary from fine rapid shimmering to slow rhythmic to-and-fro jerking, and it may be paroxysmal or continuous. All this time, too, the child's mental state has been gradually dilapidating. Initial seeming disinclination to speak has, by stages, become a definite poverty of words, and ultimately a global aphasia, and what was at first a mild lack of interest in surroundings has turned into profound apathy towards people and objects. Signs to suggest blindness and deafness of cortical origin declare themselves, and feeding becomes increasingly difficult. The child has now arrived at a state of frank decerebration in which it may remain for a number of weeks before death comes finally from failure of the medullary centres, perhaps with terminal bronchopneumonia.

## Differential Diagnosis

As to differential diagnosis during life, there are not many possibilities which have to be considered. The relatively slow march of the disease, and its ingravescent onset, rule out any of the ordinary forms of virus encephalitis or allergic encephalomyelitis. It is less easy to exclude subacute sclerosing or inclusion body encephalitis, but the recorded cases of these conditions have been in older age groups, and furthermore, more or less rhythmically recurrent and symmetrical myoclonic jerkings of the limbs, trunk and head are found in them which are not a feature here. Both also show rather characteristic EEG phenomena in the shape of repeating high amplitude complexes, appearing every few seconds against a relatively flat potential background. The only available EEG data in metachromatic leucodystrophy seem to be in my own case, where serial traces showed not this pattern, but a general dysrhythmia which came to be increasingly dominated by delta activity, with some scattered sharp waves at a late stage. If this can be taken as a paradigm, then it suggests that the electrographic signs can be useful in differentiation. Another small point of distinction is the C.S.F., for in leucodystrophy the protein is raised, usually with increased globulin, and without cellular increase, but the Lange curve does not show the first zone precipitation met in inclusion and sclerosing leuco-encephalitis.

That leaves over Schilder's disease which can only be distinguished at autopsy or perhaps by cerebral biopsy, and cerebral lipidosis such as amaurotic familial idiocy, but there the early presence of retinal pigmentary change or macular spot should usually allow recognition.

## Pathology

Pathologically the gross appearance of the brain is normal, though in handling it feels unduly resilient. Microscopic sections show that there is massive demyelination in the cerebral hemispheres, which includes the internal capsule and corpus callosum but tends to spare the juxta-cortical arcuate fibres, and the fibres of the optic radiation; there is also fall-out of intracortical radial fibres. The white matter of the cerebellum suffers heavily, too, and so do the descending fibre systems of the brain-stem and spinal cord. The destructive process is one which affects axones as well as their myelin sheaths, and there is pronounced overgrowth of fibrillary astrocytes. There is relative absence of sudanophil products of myelin breakdown, and a striking feature is the scattering of unusual granular material throughout the zones of white matter damage. It is mostly visible in rounded clumps, the so-called granular bodies, in some of which a nucleus can be made out, and it is evident that they represent degenerate microglial phagocytes. It is also seen discretely as a finer dusting, and may be found occasionally in the cytoplasm of swollen astrocytes and within the bodies of some nerve cells. It exhibits the property of staining metachromatically, in various shades of pink or dull red with toluidine blue, instead of giving the normally expected (orthochromatic) blue coloration. Histochemically it is a lipid substance, probably not a single one but of two or three different kinds, one at least being a glycolipid.

### Pathogenesis

There is uncertainty about the origin of this material. There is a metachromatic phase in the breakdown of myelin in normal (Wallerian) degeneration of nerve fibres, although it is only transitory (Einarson and Neel, 1942), and it might therefore arise from arrest of myelin catabolism short of its ordinary end-point because of an enzyme defect. This notion was favourably considered by Kaltenbach (1922), though he also put forward as an alternative the possibility of a fault in myelin anabolism, leading to accretion of a substance impossible to be dealt with further by normal metabolic routes. The trend of current opinion, however, is to interpret it as deriving from an inborn error of lipid manufacture in the nervous system, affecting myelin synthesis tangentially instead of in the direct line (Diezel, 1957).

This thesis naturally suggests that late infantile metachromatic leucodystrophy may have nosological alignment with the cerebral lipidoses as a general class, a notion that was originally discussed in a different context by Witte (1921) and more recently by Norman (1947), and it has received some biochemical support from the studies of Edgar (1957). Whether the presence of metachromatic material in the viscera, which has been noted in several cases (Brain and Greenfield, 1950; Leslie, 1952; Bertrand *et al.*, 1954), can be taken as an index of widespread lipid mishandling is not yet clear, and it may only represent an overflow phenomenon. Nevertheless the relatively frequent existence of renal deposits is of practical importance, as it provides a possible method for diagnosis of the disease during life by examination of the urine, and Austin (1957) has just reported a technique which he has developed and used successfully.

The recently published report of the Antwerp colloquium (van Bogaert *et al.*, 1957) gives promise that we are now on the edge of clearer understanding of the leucodystrophies, from information obtained by the use of new histochemical and biochemical techniques to eke out the findings of classical morbid anatomy. It now seems certain that the late infantile type of metachromatic leucodystrophy is distinct both in microanatomy and histochemistry (Diezel, 1957) from the acute infantile globoid cell leucodystrophy of Krabbe type, though it may not be so sharply divided from the juvenile forms described by Scholz (1925) and others, or the chronic cases recorded by Witte (1921), Carrillo (1934), van Bogaert and Dewulf (1939) and Norman (1947), in spite of their pronounced clinical differences. Further, the work of von Hirsch and Peiffer (1957) indicates that the histological division of metachromatic from non-metachromatic leucodystrophies, having the same morphological characteristics otherwise, is invalid. Lastly, with reference to the absence of the oligodendroglia in late infantile metachromatic leucodystrophy, which has been suspected as a possible prime factor in its causation, no definite answer is yet possible, but recent evidence diminishes the likelihood of their being directly concerned.

## DISCUSSION: THE BREECH

**Dr. G. F. Abercrombie** (London):

*The Timing of External Version*

Everyone would agree that a normal vertex presentation in the care of an unaided midwife is a very much safer proposition that a breech delivery in a specialist hospital [1], but we all know that some breech presentations, if allowed to persist too long, cannot be converted to vertices, even with the help of anæsthesia. The question is whether, by care and thought, a breech presentation, if it be the only complication, can invariably be avoided. In 1939, I advocated early external version [2], i.e. about the 30th to 32nd week, and up to that time all my private patients, 180 in number, had presented a vertex at confinement, although a breech presentation had been observed during pregnancy in 36, and external version had seemed to be necessary in 16.

In the 100 confinements which I have since attended, there were two breech deliveries, one in a primigravida who was overdue and the other in a multipara already in labour when first seen. There were 32 other breech presentations. Of these, 16, including one twin, assumed, unaided, a final vertex position by or shortly after the 32nd week; in 10 others, one of which required an anæsthetic, a single external version was done, and the resulting vertex presentation persisted, as far as I know without relapse, until delivery. My present policy is to watch these patients very carefully from the 30th week onwards. If, on any given occasion, I think I could turn easily, I wait another week, but as soon as I feel that, if left any longer, I might fail without anæsthesia, I turn at once. Before resorting to anæsthesia, I try to turn on two or three occasions at intervals of two or three days. Quite often, if I fail at a first attempt, I may succeed a little later.

There remain 6 pregnancies in which spontaneous version from breech to vertex had already taken place, but in which the breech presentation reappeared. In 3 of these a single external version was enough. The next, a 4-para, showed a very unstable presentation.

In her third pregnancy spontaneous version to vertex was noted at the usual time, normal labour occurred two days early, the baby weighed 5 lb. 15 oz., and the cord was tightly round the neck two and a half times. In the next pregnancy, a breech presentation recurred and persisted into the 36th week, when it was corrected. Two more spontaneous versions and two more external versions brought us to the 41st week, when I invited a consultant to see her. He queried her dates, but consented to a final external version followed immediately by induction with a Drew Smythe catheter. Three days later she delivered herself and the baby weighed 5 lb. 12 oz.

I never discovered why this presentation was so unstable, but I do not believe it was because the cord was round the neck once. The last patient set me a series of problems.

In her first pregnancy, she took me completely by surprise, for a breech was found in the 39th week long after spontaneous version from breech to vertex had taken place; in her second, similarly, external version corrected a relapsed spontaneous version. I know nothing of her third pregnancy, after which, on account of backache, repeated miscarriages and a retroverted uterus, a Gilliam's operation was done. She soon became pregnant again. The fœtus was uncommonly mobile and the cervix, naturally, very high in the pelvis. After three versions between the 32nd and 36th weeks, a vertex was found consistently until she was a week overdue, when the breech presentation

unexpectedly recurred and was corrected. Fortunately she went into labour a few days later and the baby weighed 9 lb. 4 oz. The same sort of thing occurred in her final pregnancy for the breech presentation recurred in the last week before term, but could not be turned without anæsthetic. Accordingly, after consultation, external version was done under an anæsthetic, and a pint and a half of liquor amnii was drawn off with a Drew Smythe catheter. Even then, and in spite of a firm binder, the head, still very high, tended to float away into an iliac fossa. Delivery was easy and the baby weighed 8½ lb., but the cervix was torn on both sides and a very severe post-partum hæmorrhage followed, which required another anæsthetic and a blood transfusion. Perhaps we tried to be too clever.

My conclusion is that, if one has the opportunity to observe a single fœtus in a normal uterus from the 30th week onwards, breech presentation can, when necessary, be eliminated, usually by a single well-timed external version. On rare occasions only the manœuvre must be repeated, the possibility of the cord being tightly round the neck being borne in mind [3]. I admit that, in order to be sure of eliminating the 3% or 4% which would otherwise persist, I find myself constrained to perform version in a high proportion, but as anæsthesia is so seldom required, the obstetric gain is very great. Even when the obstetric factors are thoroughly unfavourable, a vertex presentation can always be obtained, but whether, when confronted with an unusually unstable presentation, it is wise to induce labour, simply in order to expedite delivery, is a much more doubtful proposition.

*The figures for the two series together are as follows:*

| | | | | |
|---|---|---|---|---|
| Pregnancies | | | | 280 |
| Breech presentation | | | 70 | |
| Corrected by spontaneous version | | 37 | | |
| Corrected by external version | | 31 | | |
| Without anæsthetic | 27 | | | |
| With anæsthetic | 4 | | | |
| Too Late! Therefore breech delivery | | 2 | | |

**Mr. John Hamilton** (Liverpool):

In 1933 the late Dr. J. W. Burns and Dr. Charles McIntosh Marshall evolved a technique of breech delivery which, with slight modifications, has been the method used in the Liverpool Maternity Hospital from that time. The background of the method of delivering the aftercoming head has an interesting story attached to it. The late Dr. Burns was endeavouring to deliver an aftercoming head through the brim and eventually gave it up as hopeless. He had watched the infant hanging down for some time when suddenly the infant appeared to drop. Seizing it by the legs he swung it up and over the mother's abdomen and to his surprise delivered it with great ease.

In the first twenty-four years of this method of delivery there have been 1,306 infants weighing over 4·9 lb. delivered by the vaginal route as a breech. The fœtal mortality during that period has been 4·2% but there has been a steady improvement throughout the period and the fœtal mortality for the past five years has been 2%. As, during these twenty-four years, there have been some 30+ registrars who are mainly responsible for the deliveries and some of whom have not had any great experience of breech delivery I feel that it speaks well for a routine that has been evolved over the past twenty-four years.

I feel that it should be accepted that elderly primigravida and any long-standing case of infertility should not be allowed to have a vaginal delivery.

A careful assessment of the pelvis clinically and, if necessary, radiologically is essential, In addition, an estimation of the size of the infant is desirable. An obviously small pelvis with a large infant may well contra-indicate vaginal delivery. I do not believe that a large infant *per se* is a cause for alarm—it is the relative size of the infant and pelvis that matters.

There is a widespread belief that there is more difficulty in the delivery of a breech with extended than with flexed legs. Given a reasonable size of infant and pelvis, labour, in the case of the extended legs, is slightly more rapid. This is explained by the fact that the breech with extended legs fits well into the lower segment and acts as a perfect dilator of the cervix.

The average length of labour where the legs are extended is one hour less than when they are flexed. This is important in the conduct of the modified trial of labour in a breech since the trouble met with in breech with extended legs increases in direct ratio with the length of labour. If the length of the first stage of labour in a breech with extended legs is unduly prolonged it means that one is either faced with an inco-ordinate uterine action, or there is uterine inertia usually due to an excessive size of the infant. I have always been impressed with the comparatively infrequent uterine inertia in breech presentations unless the breech is of a large size, which has convinced me that most of the so-called inco-ordinate uteri have some underlying factor present.

Prolonged labour, whether the breech or the vertex is presenting, will give a high risk to the fœtus and may require a decision to change the mode of delivery from vaginal to abdominal. As I have mentioned earlier the size of the infant should be assessed clinically and radiologically. If the impression is one of great size, a trial labour of the modified form is started but at any time preparations are made for Cæsarean section. During the past twenty-four years, 214 Cæsarean sections have been done in the Liverpool Maternity Hospital for breech presentation. Of these there were 66 done on account of age, 61 because of contracted pelvis and 49 because of large infant and inertia.

The large infant that is going to give rise to trouble, fortunately in nearly every instance, shows its size by producing a uterine inertia. If the infant is evidently large, the cervix ripe and the breech fitting the cervix well, there is a place for induction of labour before term. This is, I feel, a safe procedure in case of breech with extended legs and if the conditions for induction are satisfied at the 38th week, there is I feel no contra-indication and, in fact, many advantages where an obviously large infant is present.

I will say at the outset that there is only one place for breech delivery, whether multigravida or primigravida, and that is in hospital.

The conduct of the 1st stage of labour is largely that of the conduct of a normal vertex, bearing in mind the fact that uterine inertia is an unfavourable sign and may lead one to consider whether a vaginal delivery is really the correct method to be employed.

The conduct of the 2nd stage can be divided into the expulsive part and the actual delivery. It is, I believe, important not to encourage a patient to bear down until it is certain that the cervix is fully dilated. This is especially important in cases of breech with flexed legs as, with prolapse of the foot through the cervix into the vagina, the patient may feel a desire to push although the cervix is not fully dilated. There is undoubtedly no more important cause of trouble, especially with the arms, than an incompletely dilated cervix.

At the Liverpool Maternity Hospital I found that the average length of the second stage was one hour. Where the second stage was unduly prolonged there was an increase in the number of stillbirths; some of these were due to faulty selection of cases for vaginal delivery but some were due to fœtal anoxia during prolonged labour. Therefore, an unduly prolonged second stage should be a warning. Delay in the second stage is due to a faulty selection of case, namely, too large a baby for too small a pelvis, or to the splinting action of the extended legs not allowing the lateral flexion of the trunk. If there is delay in the second stage a decision must be made between breech extraction and Cæsarean section.

We must now turn to the actual delivery of a breech and the method I propose to describe is, in the main, the Burns-Marshall technique. We find that very soon after full dilatation, the anterior buttock will be visible at the vulva and then the patient is encouraged to bear down. She is thus encouraged until the anus is visible. At this stage the time for delivery is at hand and the patient is placed in the lithotomy position. I would like to stress again that a breech delivery should be a set operation and, in my opinion, partly conducted under anæsthesia which should be complete by the time the shoulders are born.

When the buttocks are distending the perineum and the anus is visible is the time for the performance of an episiotomy. This is done after infiltration along the line of incision with 1% procaine. The actual incision of the episiotomy is timed to coincide with an expulsive effort on the part of the mother. Further expulsive efforts on the part of the mother will push both buttocks past the vulva but it may be necessary at this stage to assist slightly by gentle groin traction. After the buttocks are born the thighs can then be abducted and the knees flexed thus delivering the body to the umbilicus. At this stage a loop of cord is pulled down, largely to make certain that there is sufficient free cord to make delivery uncomplicated by cord entanglement. At this stage, also, anæsthesia is induced with intravenous Pentothal.

From this stage we have to complete the delivery, avoiding extended arms and an extended head. It is extremely rare to see extended arms in a radiograph of a breech and it is my belief that they are more often produced by faulty technique. The commonest cause of producing extended arms is bringing the shoulders through the brim in the transverse diameter.

After anæsthesia has been induced, the child is grasped either by the feet or by a grip of the thighs using a sterile towel to avoid the slippery surface which is produced by meconium, and not to prevent premature inspiration. Steady—and I emphasize steady—traction is now exerted towards the floor. This traction is continued until the anterior scapula appears. Considerable force is used during this traction. Once the scapula appears, the anterior arm can be released by hooking it out with the fingers. As soon as the anterior arm is released the child is lifted upwards by the legs away from the side on which the back is situated and the posterior arm is gently extracted.

The child is then allowed to hang down in order that its body weight may aid flexion. This will aid in the engagement of the aftercoming head. There seems to be some doubt about how long the body is allowed to hang. I think I can safely say that we allow it to hang while we wash the meconium off our gloves. If the head is not descending it may be necessary to apply suprapubic pressure. This should be done with care and the knowledge that the flexion is required for the head to pass through the pelvis satisfactorily. There should, therefore, be more pressure on the sincipital than the occipital side in order to favour this flexion. When it is clear that the head has entered the cavity of the pelvis the infant is grasped by the feet and, maintaining traction, the feet are brought up in a wide arc through 180 degrees. Traction at this stage is essential in order that the head can pass through the pelvis in flexion. If no traction is applied and the feet merely lifted up over the mother's abdomen, the neck of the fœtus will be broken. At the same time that traction is applied I usually keep up suprapubic pressure as I believe that flexion can be maintained more easily that way. When this traction through 180 degrees is complete the mouth will be appearing at the vulva and either by pulling back the perineum or putting in a Sim's speculum, an airway can be provided. I, personally, at this stage always apply Simpson's forceps as a routine. The main advantage to the aftercoming head of forceps is the absolute control one can obtain over the rate of exit.

Some of the damage to the fœtal skull can be caused by a sudden rebound of the skull from a very rapid exit and as once the mouth is at the vulva there is ample time for delivery, advantage should be taken of this available time.

In summary, I would like to emphasize one or two points which I think are essential in breech management:

(1) Careful selection of cases for vaginal delivery.
(2) Regard breech delivery as a set operation requiring a team of obstetrician, assistant and anæsthetist.
(3) Rapid induction of anæsthesia as a routine in all breech delivery—it is often too late, if trouble is encountered, to start induction.
(4) Careful guidance of the shoulders through the brim.
(5) Allowing the body weight to bring the head through the brim.
(6) Firm traction on legs bringing head to the outlet.
(7) Forceps to the aftercoming head more to control rate of exit than to speed rate of exit.
(8) And finally, and most important of all, traction, when applied, should be even and not jerky.

MARSHALL, C. M. (1934) *J. Obstet. Gynæc., Brit. Emp.*, **41**, 930.

**Mr. J. H. Peel** (London):

I wish to discuss the part played by external cephalic version as a means of lowering firstly, the incidence of, and secondly the overall fœtal loss due, to breech delivery.

*The Justification for External Cephalic Version*

The paper published by Vartan (1945) established external cephalic version as a sound physiological procedure. He emphasized that up to the 32nd/33rd weeks of pregnancy, it was normal for the baby to lie as a breech, but that by that date the majority of these had undergone spontaneous cephalic version. A small percentage, unable to turn spontaneously, remain, either because there is very little liquor, or as the result of the legs being extended so that the breech engages in the pelvis by the 32nd week. In performing external cephalic version, one is simply aiming to mimic the natural process of spontaneous version, and the timing of this procedure may have to be varied, depending on the amount of liquor, size of baby and the tone of the uterine muscle. It is seldom advisable before 33 weeks, but in the primigravida it should not be left after the end of the 35th week. White (1956) showed that spontaneous version does occur in some 30% of primigravidæ after the 34th week, but hardly ever after the 36th week.

The dangers of external cephalic version to the fœtus have been emphasized by several writers, particularly if anæsthesia is used. Nevertheless there are several series of cases

published which show that these dangers can be reduced. Clayton and Peel (1948) 1·7% fœtal loss. Freeth and MacVine (1951) 1·4%. Dalley (1952) no fœtal loss in 330 cases of external version without anæsthesia.

Table I shows my personal series of 1,089 cases over a ten-year period 1947/57, and the

TABLE I.—MATERIAL ANALYSED. ALL BOOKED CASES

| | Total deliveries | Version attempted | Anæsthesia used | Successful version | Fœtal loss due to version |
|---|---|---|---|---|---|
| (1) Personal Series 1947/1957 | 1,089 | 52=4·8% | 6=11·5% | 49=94·2% | 0 |
| (2) K.C.H. Series 1949/1957 | 7,816 | 411=5·2% | 147=35·7% | 375=91·2% | 6=1·4% |

second series of 7,816 booked cases at King's College Hospital between 1949 and 1957. In my own series version failed in 3 cases, 2 of which were subsequently delivered by Cæsarean section for placenta prævia and age, and in only one was vaginal breech delivery necessary. In my own series there was no fœtal loss due to version, but in the K.C.H. series there were 6 babies lost, giving a total of 1·4% (Table II). Two of these can, however, be excluded as version did not cause fœtal death, which reduces the mortality to 0·9%.

TABLE II.—K.C.H. SERIES. STILLBIRTHS PRESUMED DUE TO EXTERNAL CEPHALIC VERSION

| 5 | Intra-uterine death | Version 36 weeks (twice) | With anæsthetic | |
| 6 | Intra-uterine death | Version 38 weeks | With anæsthetic | |

The second argument which is used against external cephalic version is that it fails to lower the incidence of breech delivery at term because of the high incidence of spontaneous version. The incidence of breech delivery at term is between 3% and 4% in institutions not practising external cephalic version. Table III shows that in 7,816 total deliveries

TABLE III.—K.C.H. SERIES. SINGLE BREECH DELIVERIES (AFTER 34 WEEKS' GESTATION)

| Total deliveries | Breech deliveries | Failed E.C.V. | E.C.V. not used | Undiagnosed before labour |
|---|---|---|---|---|
| 7,816 | 77=0·98% | 36 | 29 | 12 |

there were 77 single breech deliveries after 34 weeks, i.e. below 1%. External cephalic version failed in 36 cases, in 29 it was not attempted, and in 12 the diagnosis was missed before the onset of labour. In my own series there were only 5 breech cases, an incidence of 0·5% (in addition to the 3 cases mentioned above, there were 2 delivered by Cæsarean section in which external cephalic version was not used). Fell (1953) showed an incidence of breech delivery of 1·35% in an institution performing routine external cephalic version. White (1956) attempted to prove that even after 34 weeks spontaneous cephalic version occurs so frequently (50% approx.) as to make external cephalic version by the obstetrician unnecessary. The figures that he quotes, an incidence of breech delivery of 3·2% after the 34th week, completely disprove the very point which he set out to make.

Another argument that is used against external cephalic version is that the results of vaginal breech delivery are now so good that it is not necessary to do it. However, the low fœtal mortalities quoted (between 1% and 3%) have been achieved in two ways:

(1) By emphasizing the abnormality of breech presentation, to the extent that senior and experienced obstetricians are always present at the delivery.

(2) By such careful selection of cases for vaginal delivery that the Cæsarean section rate is very high. Table IV shows that in one series it is 12·4%, and in the series of Law

TABLE IV.—CÆSAREAN SECTION RATE (BREECH PRESENTATION)

| Authority | Total cases | Cæsarean section % |
|---|---|---|
| Cox (1950) | 1,004 | 12·4 |

| Weeks gestation | Total cases | Successful | |
|---|---|---|---|
| 32–33 | 7 | 5=71·4% | 50=86·2% |
| 34–35 | 51 | 45=88·2% | |
| 36–37 | 55 | 34=61·8% | 61=68·5% |
| 38–T | 34 | 27=79·4% | |

(1955) it is 13·3%. It is usually stated that the indication for Cæsarean section is not the breech presentation but an associated condition such as contracted pelvis. However, had the baby been presenting as a vertex, vaginal delivery would often have been possible. The weakest link in the argument that a breech is as safe as a vertex delivery is the readiness with which Cæsarean section is undertaken. By way of contrast I have worked out the incidence of Cæsarean section in our own group of cases, which would have reached term as breeches had external cephalic version not been carried out. There is an incidence of Cæsarean section of 5·7%, which includes 9 after successful version, which is about half the usually quoted figures in institutions not practising external cephalic version.

It is argued that if external cephalic version is used routinely, the number of breech deliveries that become available for teaching students, residents and registrars will be very limited. This is not a justifiable argument, and negatives the whole purpose of antenatal care.

By way of conclusion I would like to stress a few of the important points relative to external cephalic version:

(1) Early diagnosis of the breech presentation is essential (32 weeks in the primigravida). When there is relatively little liquor, a deeply engaged breech with extended legs at 32 weeks is easily missed, and that is just the case in which early version is essential if it is to succeed. It should be attempted in the first instance without anæsthesia, but with anæsthesia at or very soon after the 34th week.

(2) In performing external version, work mostly on the breech rather than on the head. The direction for version is the one in which the baby will most easily turn, and frequently when the legs are extended in a primipara, the baby turns more easily if it is moved, not in the direction in which it is looking, but in the opposite one.

(3) Anæsthesia. We have employed succinyl choline hydrochloride (Scoline) 50 mg., after the patient has received premedication with Omnopon or pethidine, and been put to sleep with a small dose of Pentothal. Ether anæsthesia is rarely necessary.

(4) It requires just as much skill and experience to know when to desist from attempts at external version as it does to know when to undertake vaginal breech delivery. Too much force is unnecessary.

(3) There are certain definite contra-indications to external cephalic version:
(i) Pre-eclamptic toxæmia because of the danger of placental separation.
(ii) Suspected cases of placenta prævia.
(iii) A scar in the uterus from previous classical Cæsarean section or myomectomy.
(iv) A congenitally abnormal fœtus.
(v) Any associated condition which necessitates Cæsarean section in any case.
(vi) Multiple pregnancy.
(vii) Unicornuate uterus.

Inevitably there must remain a hard core of breech cases where version is either contra-indicated or fails. It is important to assess all cases with special reference to contraction of the pelvis. A breech delivery is relatively safe if there is a roomy pelvis, but it is a highly dangerous procedure if the pelvis is contracted. In cases of minor degrees of contraction of the pelvis or an abnormally large baby, it is wiser to err on the side of doing a Cæsarean section rather than risk vaginal delivery, but it is particularly in this last group of cases that external cephalic version really does justify itself. Minor degrees of contracted pelvis which are suitable for a trial of labour if the presentation is a vertex, and which so often end in successful vaginal delivery, are the most frequent cause of fœtal death in this type of breech delivery. If the incidence of Cæsarean section is to be kept within reasonable limits, external cephalic version should certainly be attempted in this group of cases.

**Mr. David Methuen** (Oxford):

I should like to present a series of cases of breech deliveries conducted in the Area Department at Oxford and to discuss the problem of anæsthesia for this type of delivery.

During the five years from the beginning of 1952 to the end of 1956 there were 448 breech deliveries out of a total of 15,500: an incidence of 2·9%.

There were 48 stillbirths and 25 neonatal deaths giving an uncorrected perinatal mortality of 16·3% compared to an overall fœtal loss of 3·5%. The Cæsarean section rate was 8% and there was no maternal death.

Table I shows the fœtal loss for mature and premature babes of primiparous and multiparous patients:

TABLE I

| PRIMIPARÆ | | MULTIPARÆ | |
|---|---|---|---|
| | >5 lb. 8 oz. | | >5 lb. 8 oz. |
| 139 | 4 Stillbirths | 156 | 8 Stillbirths |
| | 0 Neonatal deaths | | 2 Neonatal deaths |
| PERINATAL MORTALITY .. | 2·8% | PERINATAL MORTALITY .. | 6·4% |
| | <5 lb. 8 oz. | | <5 lb. 8 oz. |
| 50 | 9 Stillbirths | 103 | 27 Stillbirths |
| | 8 Neonatal deaths | | 15 Neonatal deaths |
| PERINATAL MORTALITY .. | 34% | PERINATAL MORTALITY .. | 40·7% |

In these 448 deliveries general anæsthesia, local analgesia, or a combination of the two was used 208 times. More than half the cases required only general analgesia.

Pudendal block was used for 37·5% of the deliveries and I would suggest that, in the interests of the mother and baby, this method of analgesia or epidural analgesia should be used more frequently for the following reasons, which should be emphasized and re-emphasized.

Firstly the risk of inhaling regurgitated stomach contents is eliminated and secondly transplacental narcosis is diminished. This is particularly important for the premature baby and Hingson (1947) has shown how the premature neonatal death-rate can be reduced by using caudal analgesia. Prematurity is a common complication of breech delivery and it occurred in 34% of the cases in this series.

During the last twelve months in our unit at the Radcliffe Infirmary 90% of all operative vaginal deliveries and 93% of breech deliveries have been performed either under pudendal block or epidural analgesia.

For an assisted breech delivery local infiltrative analgesia is the safest method to use and in my opinion is the anæsthetic of choice for such deliveries. The method used is to combine blocking the pudendal nerve with paravaginal and perineal infiltration. Under it forceps may be used to deliver the after-coming head and an episiotomy can be made and repaired painlessly. We have now used epidural analgesia 339 times in all and our experience with it for 24 breech extractions without fœtal loss has been very satisfactory. The technique employed is to insert a number 15 Lauer caudal needle through the sacro-coccygeal membrane. A fine nylon tube is passed through the needle which is then withdrawn. For effective analgesia to be obtained the tube must be passed for a distance of 5 to 6 in. so that the injection will be made above the lumbo-sacral junction. Below this the level of analgesia may be inadequate. A test dose of 2 c.c. of anæsthetic solution is injected. If the theca has been inadvertently punctured spinal anæsthesia will result. That this has not happened is checked after three minutes by demonstrating movements of the legs and feet.

The full anæsthetic dose of 20–25 ml. of 1% Xylocaine and adrenaline 1 : 100,000 is injected. Within minutes, using this preparation, analgesia is induced adequate for dealing with any difficulty associated with extended legs, the arms, or the after-coming head, and the operating conditions are ideal.

May I now stress the dangers and difficulties of this method?

Firstly the technique of correctly inserting the needle must be learned. Once the "feel" of this has been acquired the number of humiliating failures will be small.

Inserting needles and tubes carries the risk of these breaking. The nylon tubing can be autoclaved and is very tough. A tube of inferior plastic material was broken once in our series, but this has not occurred since we used nylon.

Total spinal anæsthesia is a potential risk, but should not happen if the initial test dose is carefully made.

Sepsis has not been encountered and hypotension has given rise to no concern since the dose was reduced to 20–25 ml. of anæsthetic solution.

These complications emphasize that this method of analgesia should only be used where the necessary equipment and assistance are available to deal with them.

The only alternative for breech extraction is to use either spinal or general anæsthesia; both are best avoided.

Particularly to be condemned is to allow partial delivery to occur under local anæsthesia and then, with the patient in discomfort, distress and the lithotomy position, to induce general anæsthesia. At the end of labour, possibly with the gut dilated, the stage is set for an anæsthetic tragedy.

The recent report on maternal mortality has emphasized the dangers of anæsthesia in obstetrics and I feel sure that the avoidance of general anæsthesia and the more extensive use of local analgesia will minimize this risk in breech delivery.

I should like to thank Dr. R. Bryce Smith and Dr. J. V. Mitchell for their help and I am deeply indebted to Mr. J. Stallworthy and Mr. W. Hawksworth.

REFERENCE

HINGSON, R. A. (1947) *Curr. Res. Anesth.*, **26**, 177.

**Mr. C. K. Vartan:**

From an examination of the earlier figures at the British Hospital for Mothers and Babies it was clear that the bulk of the babies lost were in assisted deliveries. I therefore planned to induce labour in all failed version cases at the 38th week, with the object of producing smaller babies which would not need to be extracted. I have a twenty-years' experience of this practice.

A recent analysis covering ten years shows that 85 or 37·6% of the whole were induced; 62·4% were not. One fact emerges, namely, that as many women with breech presentation go into labour spontaneously at the 38th week as are, in fact, induced. The rest are accounted for by multiple pregnancy and gross prematurity. In primiparæ the average length of labour in induced cases was nineteen and a half hours and in non-induced cases twenty-four hours. The Løvset manœuvre is always used for extracting the arms. The corrected fœtal mortality in induced cases is 5·5% and in non-induced cases 8·4%. Cæsarean section has been employed five times in 226 cases in ten years.

My main indications for Cæsarean section are Rhesus-negative primiparæ; cases referred in, at or over time with big babies; elderly primiparæ who have an unpropitious labour after induction.

In an attempt to assess the state of the baby when it is born as far as the shoulders, the fœtal pulse-rate has been counted by auscultation over the heart. Graphs have been drawn which show that the rate falls to 80 and is maintained at that speed for up to fifteen minutes. I do not advocate waiting as long as this, but submit that a reasonable interval should be allowed to elapse before resorting to extraction in order to give the head time to come slowly through the pelvis. If episiotomy is necessary it should be in the mid-line.

**Mr. Gilbert Dalley** said that external cephalic version was preferable to breech delivery, especially for the occasional or less experienced obstetrician. The tempo of version was all-important.

He showed tables illustrating a series of booked confinements in the West Hill Hospital, Dartford, for the ten years, 1947–1956: there were 10,938 deliveries, of which 109 were delivered as a breech *per vaginam*. The corrected perinatal mortality for the breech deliveries was 6·3%, compared with the overall gross perinatal mortality of 2·9%. 572 external cephalic versions were performed of which 498 (87%) were successful. An anæsthetic was only used in 33 cases, successfully in primigravidæ thirteen times and in multigravidæ once, and unsuccessfully in primigravidæ eighteen times and multigravidæ, once.

Analysis of the versions according to the stage of pregnancy showed that those performed by the 35th week were successful in 91% of primigravidæ and 94% of multigravidæ, whereas from the 36th week the percentage of success dropped to 58% in primigravidæ and 79% in multigravidæ.

Versions should be done before the 35th week, in which case no anæsthetic should be necessary.

**Mr. J. S. Hesketh** said he had always been taught to avoid traction in breech deliveries and was rather concerned at the amount of traction necessary in Mr. Hamilton's method not only to deliver the arms but also particularly to deliver the head.

He wished to seek Mr. Hamilton's reassurance that in Burns' and Marshall's original papers they stated that in the delivery of the head the obstetrician should use one hand to exert traction on the legs and the other to exert any suprapubic pressure that was required.

He had always understood that by this means no undue traction could be employed and the danger of excessive traction avoided.

**Mr. Wilfrid G. Mills** said he wished to emphasize some points that had not already been given proper weight. Breech deliveries should be clearly divided into two varieties. The extended breech was an excellent presenting part, it fitted the cervix well, it allowed an easy first stage with good dilatation of the cervix and no risk of prolapse of the cord. On the other hand the flexed breech was a worse presentation with late engagement, poor dilatation after slow descent, premature rupture of membranes and frequent prolapse of cord. The former was typical of the primigravida and the latter of the multiparous patient.

He strongly subscribed to the performance of external version. He was uncertain why the opening speakers had suggested that it should be attempted at the 32nd week. He believed it should be performed whenever a breech presentation was diagnosed, provided that no particular difficulty was encountered. It might well be impossible in cases of unicornuate uterus, even at a very early stage of pregnancy.

In labour he believed that there was a place for a modified trial of labour in patients with a slight degree of pelvic contraction: a delay of over twenty-four hours before full dilatation would usually indicate a degree of mechanical obstruction to the descending breech that foreshadowed dystocia for the head, and such cases were better delivered by section. He believed that the passage of meconium in the first stage of a breech labour was indeed a sign of fœtal distress, due perhaps to compression of the fœtal end of the umbilical cord as the breech descended into the pelvic cavity.

It was generally recognized that intracranial hæmorrhage was liable to occur in the after-coming head with considerably less trauma than was necessary in cephalic presentations: the conventional explanation was that the after-coming head of the breech required extra time to allow for moulding during its passage through the pelvis. He believed that this was a misconception and that the liability to fatal hæmorrhage was due to the after-coming head being congested with all the fœtal venous blood that had been forced up during the delivery of the lower limbs through the tight vulval ring. The life-saving delay in delivery of the head acted by allowing this venous congestion to disperse as the blood flowed back into the fœtal lower extremities. The right procedure was in fact adopted for the wrong reasons.

**Dr. J. Vincent O'Sullivan** said he would like to support Mr. John Peel most strongly in his plea for external version in breech cases during the antenatal period. He, too, was sure that the breech should be turned somewhere between the 30th and the 34th week. In his hospitals the incidence of breech deliveries was 1%. If it had not been turned by the 34th week the patient should be admitted to hospital and given either heavy sedation or a general anæsthetic, including ether if necessary, to do a version.

He always took an X-ray before attempting version under anæsthetic so that he could be certain of the position of the baby.

He usually succeeded in turning the breech by making the buttocks follow the head; rarely had he been able to do it the reverse way as suggested by Mr. Peel.

A trial of labour with a breech was quite possible if the breech did not reach the perineum, when it was wiser to do a Cæsarean section. Unlike Mr. Hamilton, when he had applied forceps to the after-coming head, he straddled the baby over his right forearm and gently pulled and "rolled" the head out over the perineum, making sure that the nape of the neck was pressed close against the symphysis pubis, the Mauriceau-Smellie-Veit manœuvre with forceps.

**Mr. John Hamilton,** in reply, pointed out that he did perform external version but not under anæsthesia.

He agreed with Mr. Vartan about the place of induction of labour before term in breech presentation.

Dr. Hesketh had queried the amount of traction used in the Burns-Marshall method. It was important to keep steady traction in order to keep the head in a state of flexion.

Mr. Mills made many points to most of which he would agree. He especially agreed to the differentiation between extended breech in the primigravida and flexed breech in the multipara. He would also agree to the trial of labour in breech delivery although he preferred to call it trial breech delivery. He could not, however, agree to his view that the value of the baby hanging down is to drain blood from the brain more especially when he had earlier said that the infant was deprived of blood owing to compresson of the cord.

Dr. O'Sullivan questioned lifting up the infant before putting the forceps on to the after-coming head. The reason for this was that with the infant held up it was possible to get air into the vagina and thus allow more time for delivery. It was also an excellent way of draining the air passages of mucus.

# Section of Dermatology

President—JOHN T. INGRAM, M.D., F.R.C.P.

[*October* 17, 1957]

**Chronic Granuloma of Face.**—F. F. HELLIER, O.B.E., F.R.C.P.

A. D. D., male, aged 35.

*History.*—Three years' history of ulceration of face, said to have started following squeezing a blackhead. The condition has steadily spread despite all forms of treatment and he now has five separate lesions.

Individual lesions start as a pustule surrounded by an inflamed area. This gradually breaks down and forms an indolent inflammatory patch with ulceration which slowly spreads despite treatment. There is no history of taking bromide.

*Present state.*—There are five lesions, three on the left cheek, one on the forehead and one on the right cheek; the largest, on the left cheek, is roughly triangular, about 2 × 1½ in.; the most recent one, about three weeks old, is a little pustule surrounded by redness in front of the left ear. The largest lesion is fairly well defined, scarred, centrally depressed and crusted; it oozes a few beads of pus when pressed (Fig. 1).

FIG. 1.

*Investigations.*—W.R. negative. X-ray chest normal. Sinuses normal. Serum proteins normal. Blood count normal. B.S.R. 13 mm. in one hour. Bacteriology: Usually *Staphylococcus aureus*, sometimes sterile, once coliforms. Mantoux positive 1/1,000. Histology (several occasions): A chronic granulomatous lesion in dermis and subcutaneous tissue with small irregular areas of necrosis. There are numerous giant cells, but no typical tuberculous follicles. No tubercle bacilli found. Examination for blastomycosis negative.

*Treatment.*—A wide range of local antiseptics and antibiotics. Internally: Antibiotics, sulphonamides, iodides, steroids, calciferol, &c. X-rays have seemed to help a little but not permanently. Curetting the lesions was followed by temporary healing but after varying periods they all relapsed.

In this case the question to be answered is whether the fault lies in the soil or the seed. We have never found anything but banal organisms and I feel that this must be considered a peculiar reaction on the part of the patient. There is no evidence of what causes the peculiarity, he shows no signs of any general abnormality—his serum proteins are normal, he has no symptoms of colitis, &c. I have seen similar lesions occasionally on arms or legs and have labelled them "dermatitis vegetans". In one case curetting extensive areas on the legs led to healing, but years later the condition broke out on the arms. This man has proved resistant to all forms of treatment including curetting.

**Chloracne.**—C. M. RIDLEY, M.R.C.P.

G. M., male, aged 32. Chemical worker.

*History.*—This man has had a rash, which began on the face, since November 1956. He has felt generally ill for a few weeks.

The rash began about two months after he started work in a chemical factory. It did not clear when he was away from the factory for three months. He handles various chemicals, including dichlorphenol and trichlorphenol; he wears protective clothing and is splashed with the liquid only occasionally on the arms.

Five other men are said to have been affected in the same way for the same period of time. The others had all worked there for several months before this patient arrived.

*Treatment.—At work:* Ultra-violet irradiation and injections (? vitamin $B_{12}$). Two weeks before first attendance at hospital—bromide mixture. Since attending hospital—methionine.

*Previous history.*—No acne.

*Family history.*—No skin disease.

*On examination.—Skin:* face, external auditory meatus, back, chest, shoulders, buttocks, scrotum and to a lesser extent on the forearms: florid eruption of densely packed comedones, papules and pustules. Pigmentation of U.V.R. on back.

*Other systems* normal.

*Investigations.*—Chest X-ray normal. ESR 5 mm. in one hour (Westergren). Hb 96%; white cells 12,000 (polys. 62%, lymphos. 33%, monos. 3%). Bilirubin: 0·1 mg.%. Empirical liver function tests normal. Plasma proteins: 7·4%; albumin 4·8, globulin 2·6 grams%.

*Comment.*—The chloracne was presumably caused by dichlorphenol and trichlorphenol; no higher chlorinated phenols, other organic chlorine-containing compounds, tars or oils are handled. These compounds seem rarely to cause chloracne, but Dugois and Colomb reported a similar outbreak in 1956 in a French factory.

Probably the systemic disturbances are due to absorption, but whether the acne is brought about in the same way is still debated; that this is the case is suggested by the fact that new lesions may appear long after exposure has ceased.

REFERENCE

DUGOIS, P., and COLOMB, L. (1956) *Lyon méd.*, **196**, 446.

**Dr. H. R. Vickers:** I have seen several of these cases occurring in electricians and in workers in the chromium plating industry in which these chlorinated waxes are used. The large number of comedones are characteristic and there is an extremely slow response to treatment.

**Dr. G. A. Hodgson:** This is an odd case because the areas most involved are those which are covered by clothing when the patient is doing his job. Chloracne is usually produced by skin contact, but probably absorption can occur. Cases have been described in connexion with the manufacture of D.D.T. (Bowen, S. S., and Moursand, M. P., 1957, *Arch. Derm. Syph., Chicago*, **75**, 743) which is a chlorinated hydrocarbon product and in those cases it was suggested that in the production chlorinated compounds are formed in the process from hydrocarbons which are mixed with the other chemicals. An article by Shelley and Kligman (1957) suggests that once the chlorinated naphthalenes are no longer applied, the condition continues to erupt for some months and then eventually resolves after very many months with scarring and acne conglobata-like lesions. The article deals with the experimental production of chloracne with penta and hexachlornaphthalene (Shelley, W. B., and Kligman, A. M., 1957, *Arch. Derm. Syph., Chicago*, **75**, 689). It explained how eventually the whole of the sebaceous apparatus is turned into a keratin-producing machine. In fact, the whole sebaceous gland may disappear, but it does recover.

**Dr. R. D. Sweet:** Some four or five years ago Dr. F. A. Whitlock experienced a small outbreak of cases in Falmouth, which resulted from exposure to unknown chemicals when a ship which was carrying chemicals at Falmouth caught fire. No one knows what was produced by the combustion, but within a few weeks three or four members of the crew developed quite dramatic eruptions with large horny cysts over most of their bodies. They were all involved in fighting the fire and presumably came into brief contact with the fumes. Parallel with this case, there may have been more absorption systemically than there was contact with the skin.

**Dr. F. F. Hellier:** Workers who handle chlornaphthalene may develop general toxic symptoms such as liver damage, or local skin lesions. The former occur when the chlornaphthalene is volatilized during its actual manufacture whereas the latter occurs in the cold and is more probably a local contact phenomenon. This man has got his rash in areas beyond those of immediate contact, but it may be that chlorphenol is more volatile than chlornaphthalene and this would account for its wider distribution.

I would like to refer to the cases which Dr. Hodgson mentioned, produced artificially by Kligman

several of whom I saw last year in Philadelphia. Some patients developed very formidable lesions, spreading widely on the scalp and lasting for many months after the last application of the irritant. Admittedly these men were negroes in whom the sebaceous system is well developed, but it does seem as if some process had been set going often by only a brief exposure, which then became self-perpetuating. Kligman's work (Shelley, W. B., and Kligman, A. M., 1957, *Arch. Derm. Syph. Chicago*, **75**, 689) does show that the rash is due to local contact and not secondary to internal absorption.

**Dr. J. E. M. Wigley:** I think I brought some of the first cases of chloracne shown at this Section, during the war, and they mostly occurred in young women who were occupied in dipping parts in molten See-kay wax used for the insulation of deep sea cables (Wigley, J. E. M., 1944, *Brit. J. Derm.*, **56**, 230). There was very much less evidence of ordinary acne in those cases. The parts chiefly affected were the hair margin, the forehead, the cheeks and the lobes of the ears. Many of the lesions were cystic (resembling sebaceous cysts). The people I saw were working in a very primitive sort of factory with something like an old cauldron in which stuff was melted, and with a very inefficient dust and fume extractor. They said there was a very strong smell of chlorine throughout the whole place. The nurse who was sent there to run a small first-aid station had her department about 25 yards from the cauldron. There was no direct contact and yet within a few months she developed typical lesions, which were much more cystic than those we have seen to-day. Whether the condition is exactly the same as in this case I am not prepared to say, but we came to the conclusion it was probably due to the inhalation of or contact with the chlorine part of the vapour.

**Dr. J. S. Pegum:** In view of what Dr. Hodgson has said about the similarity of these compounds to D.D.T., I wonder whether the body treats them in the same way and when they are absorbed (if they are absorbed) they are not laid down in the fat and then slowly released. If this is so it might also account for the localization in the sebaceous glands.

**Dr. G. C. Wells:** I do not think that D.D.T. itself produces chloracne; it is surely the chlorobenzene used in its manufacture which does so.

**Dr. C. D. Calnan:** One of the points that Kligman mentioned was that the patients may get worse after contact with the substance has stopped. It is suggested that absorption may be responsible for that and for the dissemination, but I do not think this is true. Kligman favoured the explanation that the substance was spread over the skin surface; he found experimentally that if you painted a small square of skin it was spread by the clothing.

He has also dealt with the histology of chloracne in detail; this substance apparently has the power of changing sebaceous cells into keratinizing cells. I think we have something of tremendous importance to study here.

The following cases were also shown:

[*November* 21, 1957]

**Mucous Membrane Pemphigoid.**—J. H. ALLISON, M.R.C.P. (for F. RAY BETTLEY, F.R.C.P.).

Mrs. C. E., aged 73.

*History.*—For about two years she has had recurrent blisters on the scalp, and for the last ten months lesions have occurred on the skin in the region of the umbilicus. The appearance of the blisters is preceded by reddening of the skin and itching. The blisters on the scalp are followed by scarring and alopecia, and those on the peri-umbilical skin by scarring and pigmentation. Occasionally lesions have occurred over the shoulders and beneath the right breast. No blisters have occurred on the eyes or in the mouth.

*On examination.*—At various times flaccid blisters of variable size around the umbilicus arising on reddened skin have appeared. The blisters on the scalp have tended to be small, up to 0·5 cm. in diameter, chiefly affecting the vertex and frontal region. The affected areas subsequently show white papyraceous scarring.

*Histology* from a lesion in the umbilical region shows a subepidermal bulla. No evidence of acantholysis. There is inflammatory cell infiltration in the underlying dermis with some early fibrosis.

*Discussion.*—This case is shown simply to emphasize once again that "ocular pemphigus" can be diagnosed before any lesions occur on the eyes or the mucous membranes.

The diagnosis rests on the appearance, in one or a few localized areas, of a recurrent subepidermal bullous eruption, going on to scarring.

Skin involvement appears to develop in about a third to a half of all cases of this disease. 9 out of Lever's 19 cases (1944) and 2 of Church and Sneddon's 7 cases (1953) showed skin lesions. Lever's series showed intervals varying from twenty-two months to seven years between the onset of the skin eruption and the development of mucosal blisters, in cases in which the skin had been affected first.

The blisters on the skin occur almost always in one or a few localized areas. However, in one of Lever's cases the skin lesions were generalized.

**Pemphigus Vegetans.**—F. RAY BETTLEY, F.R.C.P.

This man of 52 first developed erosions of the mouth mucosa in 1953. The diagnosis of pemphigus was made at that time by Dr. H. Haber, who found acantholytic cells in scrapings. Since that time he has been treated with cortisone, ACTH and, more recently, prednisone.

In August 1957 he developed his first skin lesion: a group of blisters appeared on the front of the chest. Biopsy of these showed a typical lesion of pemphigus vulgaris. In the last two or three weeks, fresh lesions have appeared on the front of the chest, in the axillæ and in the right groin. Those in the axillæ have started to vegetate.

His present dose of prednisone is 40 mg. a day and this is evidently not controlling the eruption.

**Dr. F. Ray Bettley:** I saw this patient's vegetating lesions for the first time to-day and thought it was particularly interesting to see them at this extremely early stage.

There are two particular points about this case. One is the very long time—four years at least—between the onset of the condition in the mouth and the first skin lesion. The second point is that he seems to have escaped from control on a dose of 40 mg. prednisone. I have had no experience of treating pemphigus vegetans with steroids and that is one of my reasons for bringing the case forward now, so that I may have the benefit of members' comments.

**Dr. I. B. Sneddon:** I entirely agree with the diagnosis of mucous membrane pemphigus even though the mucous membranes are not involved. I thought the scarring on the scalp was very characteristic. I know of one case with lesions on the scalp which for twenty years were diagnosed as lupus erythematosus before they were correctly diagnosed as the lesions of mucous membrane pemphigus. No other variety of pemphigus produces scarring to this extent.

**Dr. C. H. Whittle:** Are these cases of mucous membrane pemphigoid expected to respond to steroids? In answer to Dr. Bettley's question as regards the response of pemphigus vegetans cases to steroids, we have one man, a farm labourer, who has been under control for five years and is completely controlled by very small doses—25 mg. cortisone daily—and is doing a full day's work. He was at point of death before his disease was controlled and spent nearly a year in the wards.

**Dr. E. W. Prosser Thomas:** I have a similar case at present. He could not be controlled with less than 70 mg. prednisone. He gradually improved, the dose was reduced and now it is about 20 mg. per day. He has been back at work for some months and is practically free of lesions.

**Dr. R. E. Church:** In reply to Dr. Whittle's question about the control of ocular pemphigus: in my experience one can control the skin lesions fairly easily on small doses of prednisolone but, however high the dose given, although one can obtain slight subjective improvement in the mucosal lesions, one can never induce them to heal.

**Dr. Eric Waddington:** The response to treatment with steroids may depend on the clinical variety of pemphigus vegetans. We have two patients, one of whom developed widespread bullæ on the back and many months later vegetations occurred in the flexures. She is only controlled with high dosage of prednisone, as for example in pemphigus vulgaris. The second patient has never had widespread bullæ. The lesions have always consisted of vegetations restricted to the flexures and muco-cutaneous junctions. She has completely cleared with small dosage of prednisone.

I agree that steroid therapy in benign mucous membrane pemphigoid is disappointing. In three of my patients the skin and oral lesions have been arrested but there has been no change in the ocular lesions.

(*To be continued*)

# Clinical Section

President—E. W. RICHES, M.C., M.S., F.R.C.S.

[*November* 8, 1957]

**Gummatous Ulcers with Gross Hepatomegaly and Anæmia.**—A. B. WOOTLIFF, M.B., Ch.B. (for J. M. MILLOY, F.R.C.S.).

Married woman, aged 58, caretaker.

Admitted to St. Mary Abbots Hospital on 14.10.57 with a diagnosis of "varicose ulcers of the leg".

*History.*—For one year increasing malaise and for eight weeks superficial ulceration of the left leg above the lateral malleolus. One month before admission she developed a swelling below the middle of the left clavicle which broke down forming a deep punched-out discharging ulcer. Two hæmorrhages from the leg ulcer had occurred. There was no history of alcoholism or of syphilis.

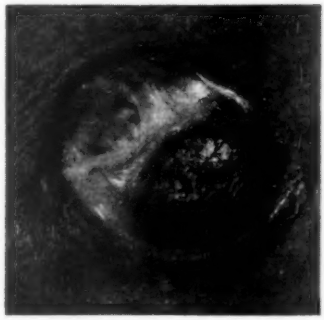

FIG. 1.—Ulcer below the left clavicle.

*On examination.*—No evidence of varicose veins or vascular disease; superficial shelving-edged ulcer on left ankle. Ulcer beneath left clavicle with serpiginous indurated edges (Fig. 1). Both ulcers were secondarily infected. The only nervous involvement was a sensory loss of stocking distribution on the left leg. Marked onychogryphosis. Abdominal examination revealed gross hepatomegaly with distended superficial abdominal veins. There was moderate sacral and ankle œdema.

*Investigations.*—Blood: W.R. and Kahn positive. Stools: occult blood negative. Liver function tests: bilirubin 0·6 mg.%: thymol turbidity 3 units: alkaline phosphatase 2·4 units: Hb 4·3 grams%: R.B.C. 2,800,000: P.C.V. 18%: M.C.V. 64 cu.$\mu$: M.C.H. 15 $\mu\mu$g: M.C.H.C. 24%: nucleated red cells 1: marked aniso- and poikilocytosis. Microcytosis +. Serum iron 23 $\mu$g.%.

15.1.58: Treated vigorously with penicillin, blood transfusions and chiropody with striking improvement. The ulcers have completely healed and the patient is ambulant, but the liver is still very enlarged.

**Addison's Disease with Glycyrrhizophilia.**—J. P. KNOWLES, M.B., B.Chir., D.Obst. (for RICHARD ASHER, M.D., F.R.C.P.).

H. L., male, aged 36.

July 23, 1957: Admitted to the Central Middlesex Hospital for investigation of suspected Addison's disease.

*History.*—Eleven years ago he had pulmonary tuberculosis, and was treated with artificial pneumothorax for five years. The disease has been inactive since.

Eighteen months ago: Patches of oral pigmentation noticed by dentist. In very good health at the time so they were presumed to be racial (Italian father and Caucasian mother).

For nine months: Weakness, fatigue and early morning dizziness.

For three months: Loss of weight (about 3 kg.), and, according to his family doctor, increasing pigmentation. (Patient and his wife denied this and put it down to a recent Mediterranean holiday.)

He admitted to no gastro-intestinal symptoms whatever.

*Clinical examination.*—Rather dark-skinned, weak, anxious man. Nipples, vaccination scar and buccal mucosa deeply pigmented. Black freckles on the back.

B.P. 110/80 lying; 100/80 standing.

*Investigations.*—Serum sodium 127·5 mEq./l., serum potassium 5·4 mEq./l., blood urea 44 mg./100 ml. Absolute eosinophil count (average of six counts) 31/c.mm. (range 19–71/c.mm.) Failed to excrete a water load.

*Progress.*—During the course of an ACTH stimulation test (Nabarro, 1954) he went into adrenal crisis. (Serum sodium 95 mEq./l., serum potassium 6·5 mEq./l., blood urea 66 mg./100 ml.) Fortunately, he responded promptly to intravenous saline and hydrocortisone and has since remained well on maintenance salt and cortisone.

Urine 17-ketosteroids (estimated after the crisis on urine collected during ACTH test) 4·6 mg./twenty-four hours (average of four days).

*Comment.*—This case was diagnosed late because: (*a*) The significance of the pigmentation was dubious and a fear of recurrence of tuberculosis seemed to explain his anxiety. (*b*) But most confusing was his denial of gastro-intestinal symptoms, which are "almost a *sine qua non* of Addison's disease" (Selye, 1949). However, after the crisis he admitted having lost his appetite for everything other than salt and liquorice sweets. For three months he had been eating up to 0·25 kg. of very salty black olives and a similar quantity of liquorice sweets daily.

Salt-craving is a well-known symptom of Addison's disease and occurred in 16% of 66 patients described by Thorne *et al.* (1942). Liquorice-craving (for which Dr. Asher has suggested the name glycyrrhizophilia) has not been described before. It is well established that liquorice has a desoxycorticosterone-like action (Molhuysen *et al.*, 1950) and it has been successfully used in the treatment of some cases of Addison's disease (Groen *et al.*, 1951; Borst *et al.*, 1953).

0·25 kg. of liquorice sweets contain about 6 grams of extract of liquorice (personal communication from Geo. Bassett & Co. Ltd., Sheffield). Cases of Addison's disease have been maintained on 3 grams to 60 grams of liquorice extract per day, the smaller quantity being sufficient when the disease was controlled.

It seems reasonable to assume that the salt and liquorice both helped in the suppression of symptoms, and that when their consumption ceased after admission to hospital this precipitated the adrenal crisis.

A preliminary, retrospective survey amongst other known cases of Addison's disease suggests liquorice-craving is at least as common a symptom as salt-craving and that either, or both, occur with sufficient frequency (about 25%) to make it well worth while asking about them specifically in any case of suspected Addison's disease.

**Pulseless Disease and Pulmonary Sarcoidosis.**—T. M. CHALMERS, M.D.

*Pulseless disease* (*Takayashu's disease*).—Pulseless disease is a syndrome caused by a progressive obliterating arteritis of the arteries to the head and neck with a compensatory development of collateral circulation. It occurs mostly in Japan where it was first described in 1908 by Takayashu (1908) and it principally affects young women. It is one of a group of diseases characterized by obstruction of the great vessels arising from the aortic arch—a group named as The Aortic Arch Syndrome by Frøvig (1946).

Clinically there is progressive ischæmia of the upper half of the body. The arms become easily fatigued, the pulses cannot be felt nor the blood pressure measured.

There may be ischæmic atrophy of the gums and the skin of the face, and because of the cerebral ischæmia strokes, faints, fits and psychic changes are common. In Japan the illness is called Takayashu's disease. Takayashu stressed the eye changes: there is often degeneration of the iris and retina or opacities in the lens or cornea; retinoscopy may reveal micro-aneurysms and hæmorrhages, the veins may be "beaded" by numerous constrictions with the venous flow noticeably slow.

Apart from the ischæmic symptoms there may be cardiac hypertrophy with hypertension of the lower limbs. The frequent occurrence of fever, tachycardia and a high sedimentation rate suggests a relationship to rheumatic or other infections but the essential cause of this illness is purely conjectural and the treatment no more than palliative.

*Case History*

Miss M. C., aged 30, school teacher.

February 1957: Clinical examination and fluoroscopy (in Madrid) said to be normal.

*History.*—April–July 1957: After working for three weeks in London as a hospital cleaner she developed painful nocturnal tingling in the hands and forearms, which subsided within a few weeks.

*Examination.*—Both radial pulses absent, brachial pulses grossly diminished. Right scalene lymph node enlarged. B.P. in arms not recordable. B.P. (popliteal) 150/70. No other significant clinical findings.

*Investigations.*—E.S.R. 30 mm. in one hour (Westergren). Blood W.R. negative. Mantoux 1:1,000 positive. Chest X-ray: bilateral hilar enlargement with widespread mottling in both lung fields. Lymph-node biopsy: sarcoid tissue.

November 1957: After treatment with prednisone 5 mg. t.d.s. for six weeks felt less tired and slight effort dyspnœa had disappeared. Chest X-ray showed considerable resolution. Arm pulses still markedly diminished. Angiocardiography revealed narrowing of the left common carotid as well as of both subclavian arteries.

She is thought to be an example of the pulseless disease (Takayashu's disease) with incidental and unrelated sarcoidosis. An excellent account of this form of arteritis is given by Ask-Upmark (1954; Ask-Upmark and Fajers, 1956).

**Traumatic Aneurysm of the Popliteal Artery in a Boy Aged 11 Years, Associated with an Osteoma of the Lower Femur. Treatment by Aneurysmectomy and Repair of Vessel Wall.**—A. M. DESMOND, F.R.C.S.

Traumatic aneurysms of the popliteal artery in children occur in modern civil practice only rarely. In the days of stage-coaches, post boys were said to develop such aneurysms from sitting on a wooden seat on bumpy roads. Usually the trauma causing the aneurysm is relatively mild. The artery is most vulnerable at the adductor opening where it is liable to be compressed against the lower femoral shaft. In this case quite minor trauma caused a small tear of the vessel because there was an osteoma at this site. Two weeks passed before the resulting false aneurysm became pulsatile and repair of the vessel with excision of the aneurysmal sac was carried out without technical difficulty.

The child had always walked slightly stiffly with his left leg.

*History.*—8.10.57: Attended casualty department, St. James' Hospital.

Twelve days ago he received a kick on the back of his left knee at football and a swelling had since developed.

***Examination*** revealed a diffuse swelling of the back of the knee which was diagnosed as a hæmatoma. No pulsation was noticed by the casualty officer. The knee was bandaged and the child sent home.

15.10.57: Attended again with pain and no diminution in size of swelling. X-ray revealed an osteoma of the lower end of femur (Fig. 1). Seen by the orthopædic surgeon who continued supportive treatment.

FIG. 1.—Showing osteoma of the lower end of femur.

FIG. 2.—Arteriogram of the aneurysm.

FIG. 3.—Post-operative arteriogram showing normal vessel continuity.

28.10.57: Attended again and now the swelling was noticed to be pulsatile and he was referred to the Vascular Clinic, St. James' Hospital. On admission he was found to have a large pulsatile swelling behind the left knee. The distal pulses were normal. A femoral arteriogram showed an aneurysm of the popliteal artery with a small break in the continuity of the artery in the centre of the aneurysmal shadow (Fig. 2).

30.10.57: An incision was made on the medial side of the popliteal fossa. The femoral artery was controlled at the lower end of Hunter's canal. The adductor magnus tendon was divided and an aneurysm the size of a tennis ball was found. The popliteal artery was controlled below it. The aneurysm was dissected out and found to communicate by a small hole in the artery. Opposite this hole was a small osteoma. The aneurysm was removed piece-meal and the osteoma chiselled off. The small hole in the popliteal artery was sutured and arterial continuity re-established. The distal pulses were normal at the end of the operation and have remained so.

A post-operative arteriogram showed normal vessel continuity (Fig. 3).

**Ectopic Phæochromocytoma.**—R. E. WILLIAMS, M.R.C.P. (for Professor M. L. ROSENHEIM, C.B.E., F.R.C.P., B. J. HARRIES, F.R.C.S., and JOHN LISTER, M.D.).

Phæochromocytomata occur in the adrenal medulla, but may occur in any chromaffin deposit, e.g. the carotid body, or in the organ of Zuckerkandl on the aorta between the mesenteric artery and the bifurcation. More than half the cases affect patients between 20 and 50 years of age, but one has occurred as early as 16 months. The sexes are almost equally affected. About 10% of cases are bilateral, 10% are extra-adrenal but lying not far from the gland and 10% are malignant (Aird, 1957).

There is occasionally a familial incidence in unilateral cases and familial occurrence with other endocrine disorders such as thyrotoxicosis has been noted.

The active secretion of the normal adrenal medulla is 80% adrenaline. The secretion from a phæochromocytoma, on the other hand, contains a high proportion of nor-adrenaline which has a much greater vasoconstrictor effect and raises both systolic and diastolic pressure, unlike adrenaline. The clinical picture is usually characteristic, and the diagnosis should be suspected on clinical grounds.

A sustained or intermittent hypertension may be produced by this tumour and the size of the tumour may occasionally be detectable clinically either by the presence of a palpable mass or a displaced kidney. The confirmation of the diagnosis rests on biochemical tests. The provocative test with intravenous histamine, in doses ranging from 0·015 mg. to 0·05 m[illegible]

is now rarely used, although this test is carried out in some centres for patients whose resting blood pressure is less than 170/110 (Sprague *et al.*, 1953). Intravenous phentolamine (Rogitine test) has been held to be a safe procedure (Helps *et al.*, 1955). In many centres where assay of pressor amines is available, it is no longer used because the sudden fall of blood pressure that constitutes a positive result may be dangerous. Pressor amines in the urine give virtual proof of the diagnosis and the test carries no risk. Unfortunately the estimation is difficult, and can be carried out only in special centres. Finally, the tumour may be localized radiologically by plain films or tomography, and perirenal insufflation with $CO_2$ or oxygen may also demonstrate a mass.

The removal of these tumours requires the most careful co-operation between surgeons, physicians and anæsthetists. Post-operative care also requires the most careful regulation of the blood pressure and a nor-adrenaline drip is usually required for about the first twenty-four hours.

*Case Report:*

Mrs. G. W. A., aged 40.

9.5.57: Admitted to hospital as a case of hypertensive encephalopathy with headache and vomiting.

*Previous history.*—Eight years ago began having attacks of palpitations and sweating followed by occipital headache and a feeling of weakness. Found to be hypertensive and thought to have chronic pyelonephritis. During the last two years the attacks had begun to occur almost daily, and the headaches had become more severe and were accompanied by vomiting.

*On examination.*—C.N.S.: Blurring of disc margins, tortuous arteries and arterio-venous nipping. Bilateral exudates with 2 flame-shaped hæmorrhages on the left. B.P. 235/160. Femoral pulses present. Apex beat in anterior axillary line, heaving triple rhythm present.

*Investigations.*—Blood urea: 25 mg.%. C.S.U.: Faint cloud of protein. Occasional hyaline casts and very occasional polymorphs and red cells. Culture sterile. Concentration and dilution test: concentrated to 1020.

ECG: Sinus rhythm. Left ventricular hypertrophy and strain. Heart X-ray: slight cardiac enlargement. Lung fields normal. I.V.P. normal.

Rogitine (phentolamine) test: Very strongly positive. Her blood pressure fell from 250/150 to 90/40 in three and a half minutes and at one stage her B.P. was unrecordable. She became deeply unconscious and on recovery from this had a nominal aphasia and was completely disorientated. She fully recovered in three days.

Urinary pressor amines: Gross excess present equivalent to approximately 400 mg./twenty four hours; mostly nor-adrenaline.

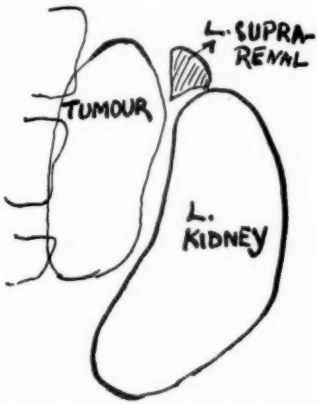

FIG. 1.—Showing a large round mass 4 in. long by 2½ in. broad lying in front of and to the medial side of the left kidney. It is in the position of the calcified region, visible in the plain films, although little or no calcification is visible in the tomographic cuts. The left suprarenal is clearly demonstrated to be separate from the mass and normal in size.

Perirenal air insufflation and tomography: Large mass in front of and medial to the upper half of the left kidney. Left suprarenal shown to be separate from the mass and normal in size. Appearances considered consistent with an ectopic phæochromocytoma.

*Operation* 29.7.57 (Mr. Bernard Harries).—Left upper paramedian incision extending as a "Y" into left costal margin. An ectopic phæochromocytoma bulging into the lesser sac and densely attached to all neighbouring structures especially to pancreas, splenic artery, cœliac axis and aorta, was removed. A large venous channel drained the tumour into the left renal vein. The left adrenal gland was normal. Right adrenal and kidney felt normal. Biopsy of left kidney taken. Operation lasted five hours. The patient was digitalized before operation. During induction the blood pressure rose to 300/190 and phentolamine 2·5 mg. was given to control this. After ligating venous drainage of the tumour nor-adrenaline was required to maintain the blood pressure, the lowest recorded pressure being 95/75.

*Post-operative progress.*—Eight hours post-operatively was found to have left hemiparesis and did not fully regain consciousness for seventy-two hours. Nor-adrenaline drip was maintained for twenty-eight hours post-operatively, a total of 30 mg. of nor-adrenaline being given.

*Subsequent progress.*—Almost complete recovery of left hemiparesis. Blood pressure 160/110. No palpitations, no sweating and no headaches. Fundi show marked regression of changes. Urinary pressor amines within normal limits.

*Histology of tumour* (weighing 76 grams).—Benign phæochromocytoma.

*Discussion.*—This report demonstrates that the diagnosis should be suspected on the clinical history; the patient described characteristic episodic attacks over a period of years. The diagnosis was virtually confirmed by the result of the phentolamine test, and the alarming sequelæ of the test emphasize its potential dangers. Confirmatory evidence was provided by the excretion of an excess of pressor admines in the urine, and tomography and air studies were used to localize the site of the tumour.

Finally, the difficult post-operative course emphasizes the importance of close collaboration between surgeon, anæsthetist and physician in the management of these cases.

B. H., male, aged 22.

*Complaint.*—Hoarseness on rotating head to the left side.

*History.*—Motor-cycle accident June 17, 1956. Contusion of mouth and lips and broken right lateral and central incisors resulted. Not unconscious and no retrograde amnesia. Eight days later sudden onset of hoarseness. No cervical pain or swelling noted. Over the next six weeks hoarseness gradually decreased until it was only present on turning head to the left. Has persisted since then.

*On examination.*—Looking to the right he can speak with a firm clear voice, but if he is asked to turn his head slowly to the left while counting aloud there is increasing hoarseness which starts soon after crossing the mid-line and reaches complete aphonia when the head is fully rotated to the left. No external abnormality. No limitation of cervical spine. Indirect laryngoscopy shows a fixed fully abducted left vocal cord but both arytenoids move normally on respiration.

*Investigation.*—X-ray of cervical spine, skull and chest shows no abnormality. Laryngeal tomogram reveals widening of laryngeal sinus with flattening of left side of larynx. W. and Kahn negative. Neurological examination normal. Direct laryngoscopy: No falling forwards of the arytenoids which are both mobile on respiration. Left vocal cord flaccid, completely abducted and bowed. Elliptical gap increased when head turned to the left. Right vocal cord moved to mid-line on phonation.

*Conclusion.*—Partial nerve lesion due to compression of fibres of left recurrent laryngeal nerve from hæmatoma or œdema is a more likely cause than avulsion of muscles from the vocal process as the symptom did not occur until eighth day after accident. Compensation by the right cord is presumably incomplete when head is rotated to the left due to an increase in the gap.

## The Calcium-containing Renal Stone [*Abridged*]

### PRESIDENT'S ADDRESS

By LESLIE N. PYRAH, M.Sc., Ch.M., F.R.C.S.

*Leeds*

THE calcium-containing renal calculus, like chronic duodenal ulcer and many cases of hormone-controlled carcinoma of the prostate and of the breast, is not a local disease of a part of the organ concerned; such a stone is usually the result of pathological changes affecting the renal parenchyma as a whole, and sometimes it results from abnormalities in organs remote from the kidney, for instance the parathyroid gland.

For a long time the attention of the surgeon was mainly concerned with the local lesion, because of the pain that it caused and because it was so often associated with infection and ultimately with serious damage to the renal parenchyma. The practical difficulties which face the surgeon, as well as the need for wider knowledge, are shown by the following case:—

Fig. 1 shows the control film and also the intravenous pyelograms of a male patient aged 56 years, who had a stone in the upper left major calyx, upon whom it was intended, after considering the pre-operative radiograph, to do an upper polar partial nephrectomy, for the relief of pain, removing the stone together with the upper major calyx in which it lay. When the kidney was exposed at operation, in addition to a stone a small, yellow, cortical tumour of 3 cm. diameter, shown later to be either a small hypernephroma or a latent carcinoma of the kind described by Franks (1954), was discovered, so the kidney was removed. A radiograph of the kidney (Fig. 2) after removal demonstrates the complicated problem which faces the surgeon:

(1) The pre-operative radiograph suggested one stone, but in fact in at least three of the calyces (upper, middle and lower) there were multiple tiny stones or calcific foci.

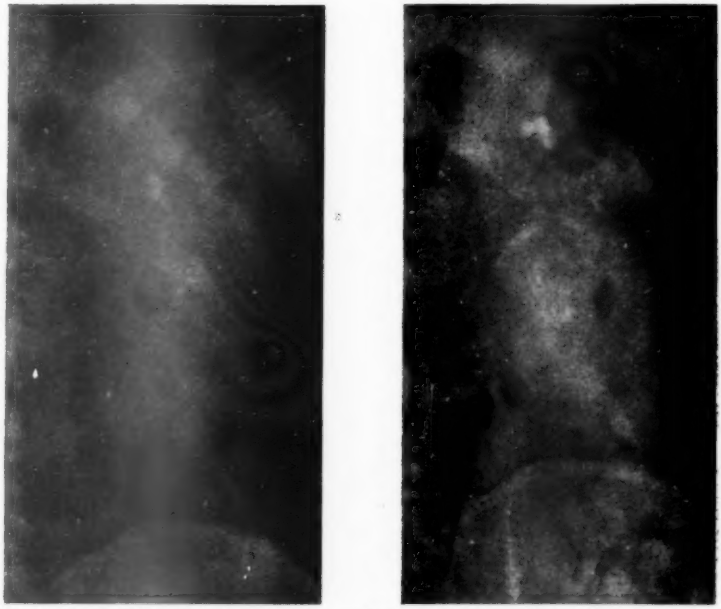

FIG. 1.—Straight X-ray and intravenous pyelogram of male patient, W. S. I., aged 56, showing a stone in the upper major calyx of the left kidney.

FIG. 2.—Radiograph of the excised kidney of the patient referred to in Fig. 1, showing in addition to the large stone in the upper calyx, multiple smaller calculi and calcific foci which had not been detected in the pre-operative radiograph.

(2) The partial nephrectomy operation which it was intended to do would not have dealt with these other gritty particles, nor have prevented their further maturation into large stones, nor indeed would any conservative operation.

(3) Although the largest stone was probably the cause of his pain, this was not certain. Nothing short of a nephrectomy would have removed all the calcific foci and thus have prevented further clinical symptoms later; yet the extent of the calcific process at the time of operation was not severe enough to indicate such a radical procedure in a well-preserved kidney had it not been for the presence of the tumour.

(4) The extensive, though mostly tiny, calcific deposits raise the question as to whether the patient may not develop stones in the remaining kidney at a later date. The second kidney is believed to be free from stones because of the control radiograph, but it may already harbour tiny calcific calyceal foci. Indeed, a guide to the prognosis in the remaining kidney is shown by his urinary calcium output after unilateral nephrectomy (Table I), which reveals a moderate hypercalciuria, unassociated with any elevation of his serum calcium; so it seems likely that the stone-forming potentiality still exists in his remaining kidney.

TABLE I.—BLOOD AND URINE CHEMISTRY IN A CASE WHOSE RADIOGRAPHS ARE SHOWN IN FIGS. 1 AND 2. There is a Moderate Hypercalciuria when the Patient is on a Normal Ward Diet. The Blood Calcium is Normal

W.S.I. ♂
Aged 59

| 17.9.56 | 374 | 1,550 | 2,215 |

The present surgical treatment of many and perhaps of most calcium-containing renal stones, however carefully the operation is done, is very often a relatively crude attack upon the disease designed primarily to relieve pain and to conserve renal function.

So it is proposed now, to examine some of the general factors (some of which may seem to be academic) concerning the stone-bearing kidney and also the calculus itself; then to refer to our limited knowledge of the general causes of stone; and finally to the attempts which are being made to prevent recurrent stone formation.

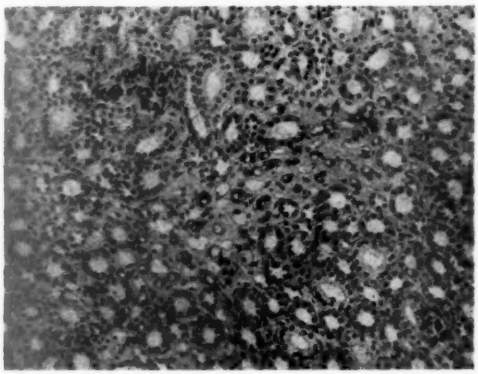
Most of the work here referred to has been done in the Department of Urology in Leeds by the clinical and research members of the Department, with important contributions from Dr. C. K. Anderson, Dr. A. Hodgkinson, Mr. B. T. Murphy and Mr. M. J. Purton.

## PATHOLOGY OF THE STONE-BEARING KIDNEY

The histological findings in the normal kidney are first compared with those found in the stone-bearing kidney at a time before it has been seriously damaged by disease. Nephrocalcinosis (by which is meant calcification in the renal parenchyma which is demonstrable

radiologically) and also renal calcification resulting from known extra-renal diseases, are excluded from consideration.

*The normal kidney.*—Does calcification occur in the *normal* kidney? The answer is that it does and very commonly. 380 apparently normal kidneys have been submitted to microscopic examination and tiny foci of calcification were present in a percentage which varied from 14% to 25% in different groups of autopsy cases according to the disease causing death; the overall incidence was about 15%. The calcific foci were sparsely scattered in the cells and sometimes around the upper collecting tubules, while a few lay within the lumina of the tubules; they are shown as black, globular deposits in almost normal cells (Fig. 3). The cause of these calcific deposits is unknown.



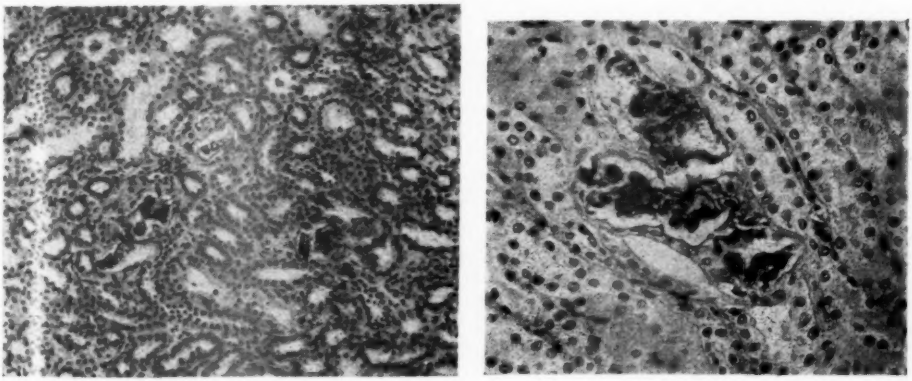


FIG. 3.—Microscopic section of a normal kidney showing two foci of calcification (stained black). ×80.

*The stone-bearing kidney.*—Examination of the renal parenchyma of partial nephrectomy specimens removed at operation for aseptic calcium-containing stones and also of stone-bearing kidneys removed at autopsy, has shown approximately a 75% incidence of calcification in the renal pyramids. The calcification here is usually found in the upper collecting tubules which may be dilated and contain calcium casts, occasionally in the convoluted tubules and also outside the tubular lumina, when they have ulcerated through (Fig. 4A and B). In the vast proportion of cases the calcific deposits in the stone cases are far more

A B

FIGS. 4A and B.—Microscopic section of a kidney which was the seat of a calyceal stone. There are multiple calcific foci in the renal papillæ (for description *see* text). A ×120. B ×200.

numerous and much closer together than the occasional sparse and scattered calcific deposits in normal non-stone-bearing kidneys. This intra-renal lesion is regarded as *the one* which is commonly associated with a calcium-containing stone.

In attempting to find the early lesion of the calyceal stone, Randall (1937) described plaques of calcium phosphate which started in the sub-epithelial region of the renal pyramids. Fig. 5 shows an example of such a plaque lying immediately beneath the

FIG. 5.—Photomicrograph of a renal papilla showing a Randall's plaque (stained black). ×93.

FIG. 6.—Thin section of a stone. The pale part at the hilus (right) of the stone is calcium phosphate derived from a Randall's plaque. The rest of the stone is laminated calcium oxalate.

calyceal epithelium and lifting it slightly as if preparatory to ulceration. Randall believed that the epithelium covering the plaque was subsequently lost and that upon the calcium phosphate nucleus thus exposed to the action of the urine, calcium oxalate or other urinary salts could be deposited, leading to the maturation of a calculus (Fig. 6). Of the many kidneys that have been examined, however, Randall's plaques have not been found with the frequency described by him.

A much rarer type of aseptic calcification of which only three or four examples have been found, is that seen in the kidney of a male patient aged 24, who had bilateral renal calculi. The urine was free from infection. Partial nephrectomy for the removal of the lower calyceal stone in the left kidney revealed, in addition to the large stone, three other calculi within a renal papilla, far removed from its calyceal epithelium (Fig. 7A). Microscopically there were a few intra-tubular calcific deposits but there was no cellular damage of the renal tubules except that caused by local trauma, and there was no inflammatory cellular response. Fig. 7B shows a deposit in a dilated duct of Bellini of some inspissated colloidal debris partly impregnated with calcium salts.

FIG. 7A.—Partial nephrectomy specimen showing two biggish and two smaller calculi located in the renal papilla itself and not in a calyx.

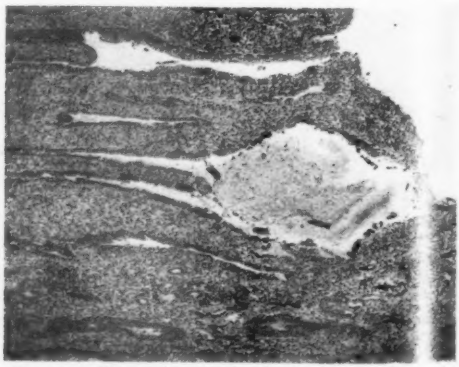

FIG. 7B.—Photomicrograph of the renal papilla the same case showing a dilated duct of Bellini containing colloidal debris partly impregnated with calcium salts (stained black). ×25.

These, then, are the three types of calcification which have been found in the aseptic stone-bearing kidney, and the first is considered to be the most important.

In the infected stone-bearing kidney, the picture is different; in such cases there is usually widespread calcification and microlith formation in the renal parenchyma, mainly in the pyramids. Fig. 8A shows the renal tract of a woman of 26 with calculous disease of both kidneys and one ureter; the clinical symptoms were not severe though she had a very resistant staphylococcal infection. The calcification here is distributed in the collecting tubules causing a complete blockage of the nephrons involved, and there are

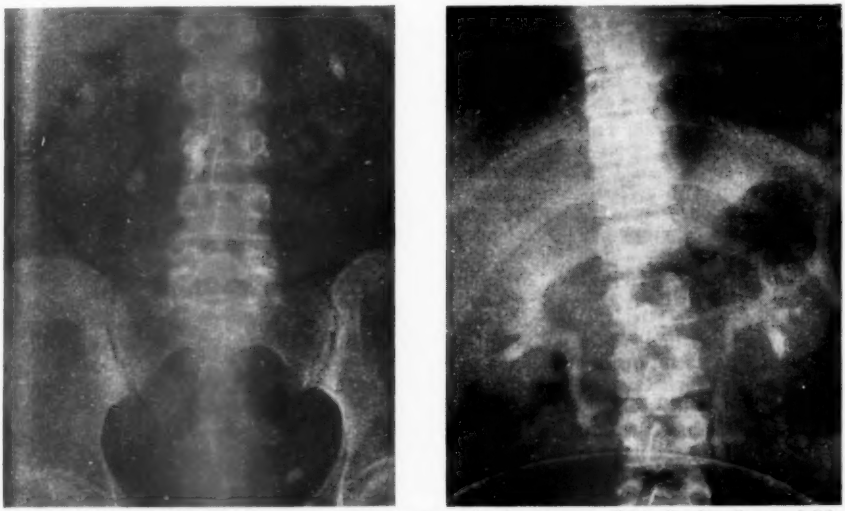

FIG. 8A.—Straight X-ray and intravenous pyelogram of urinary tract of M. G., female, aged 26. There was calculous disease of both kidneys and left pelvic ureter. The urine was infected.

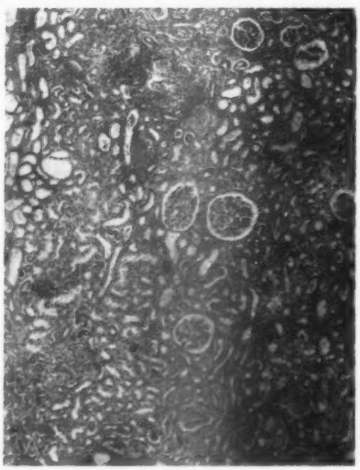

FIG. 8B.—Patchy foci of papillary calcification together with round cell infiltration in a kidney the seat of an infected stone (partial nephrectomy specimen obtained from the case in Fig. 8A). Low power.

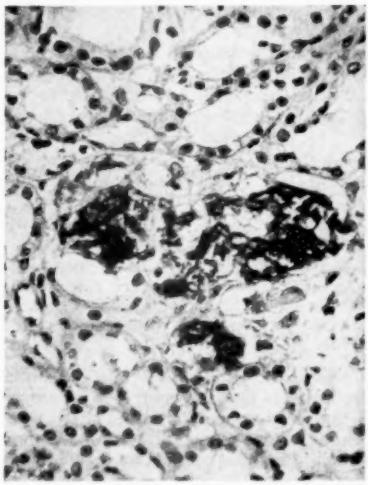

FIG. 8C.—As Fig. 8B. High power. ×233.

scattered foci in the convoluted tubules, usually the proximal ones (Fig. 8B and C). The infected cases show the grossest and most widely-spread calcification of any in the stone group; the deposits of calcific debris are larger and there is more general cellular reaction than in the non-infected stone group; there are foci of reactionary cells, often fibroblasts, without necessarily pus formation, and there is peritubular fibrosis.

Finally, calculi may be deposited in kidneys which are the seat of hydronephrosis or hydrocalycosis, possibly of congenital origin, and then stasis of particulate matter probably has an important role, intra-renal calcification not being any more common than in the normal kidney.

## Excretion of Urinary Calcium and Phosphorus in Stone Cases

Since it appears that in the parenchyma of the stone-bearing kidney there is a much greater tendency for calcium phosphate to be precipitated than in the normal kidney, the excretion in the urine of calcium and of phosphorus in patients with calcium-containing stones, and in normal controls, has been compared.

In addition to examining the urinary calcium and phosphorus in a series of cases on a low calcium diet, a larger series of urinary calcium and phosphorus on an ordinary ward diet has been examined, since the accommodation in the metabolic ward would not allow every patient with a renal calculus to be given the controlled diet. Certain conclusions have been reached regarding the practical value of the two methods, and criteria have been selected for a diagnosis of hypercalciuria on an ordinary ward diet.

*Normal urinary excretion of calcium.*—Fig. 9 shows the urinary excretion of calcium in a group of 132 normal men and 126 normal women on an intake of 800 ±200 mg. of calcium per day. The majority excreted between 100 and 200 mg. of calcium per day. On looking at the figures in greater detail, it was found that at least 90% of the men excreted less than 300 mg. per day, and at least 90% of the women excreted less than 250 mg. per day. A few individuals in each sex group excrete exceptionally large amounts of calcium, the incidence of these very high calcium values being greater in normal men than in normal women (Hodgkinson and Pyrah, 1958).

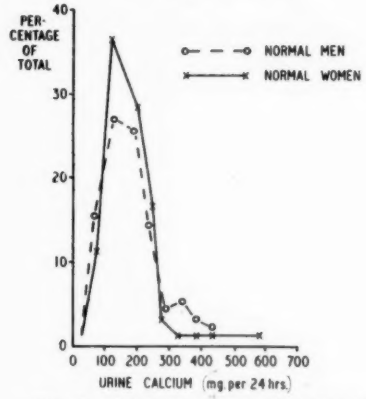

Fig. 9.—Urinary excretion of calcium in a group of 132 normal men and 126 normal women on an intake of 800±200 mg. of calcium per day (Hodgkinson and Pyrah, 1958).

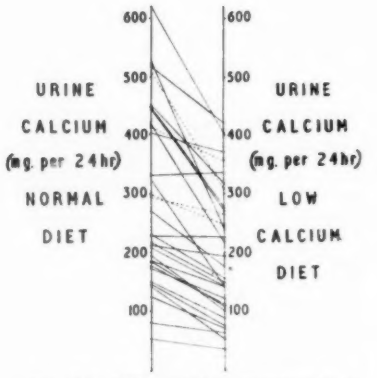

Fig. 10.—Urine calcium excretion in 32 patients on a ward diet and also on a low calcium diet (for explanation *see* text).

*Urinary excretion of calcium on normal and low calcium diets.*—The urinary calcium excretion was then compared in 32 stone patients firstly on a ward diet (containing 800±200 mg. calcium per day) and then on a low calcium diet (containing 130 to 170 mg. of calcium per day), and the results are shown in Fig. 10. The corresponding measurements for each individual on the two diets are joined by solid or dotted lines, the latter representing cases of stone in association with proved hyperparathyroidism. In general there is a decrease in the urinary calcium, but it is not necessarily a marked decrease; in some cases (in fact, in quite a proportion) there is little change.

It has already been shown that the approximate upper limit of normal for men is 300 mg. per day, and for women 250 mg. per day. If these values are accepted, then 14 of these 32 stone patients had abnormally high urine calcium values. Similarly on the low calcium

diet, it is considered that the approximate upper limit of normal is 175 mg. of calcium per day; so in the 32 patients considered here, 16 had urinary calcium values greater than 175 mg. The figures, therefore, for the incidence of hypercalciuria, when the estimations are done on a low calcium diet and also on a normal calcium diet, are reasonably close. It seems, therefore, that for practical purposes an abnormality of calcium excretion may be detected as readily with the patient on a normal diet as on a carefully controlled low-calcium diet.

*Calcium excretion by normal adults and by stone patients on a normal diet.*—Fig. 11A shows the distribution of urine calcium values for normal men compared with that of a group of 220 male stone patients. In the case of the stone patients there is a shift to the right, showing a higher incidence of hypercalciuria; 35% of the stone cases had values higher than 300 mg. compared with 10% of the normal controls.

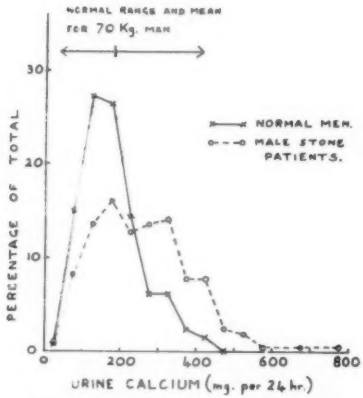

FIG. 11A.—Distribution of urine calcium values for normal men compared with a group of 220 male stone patients.

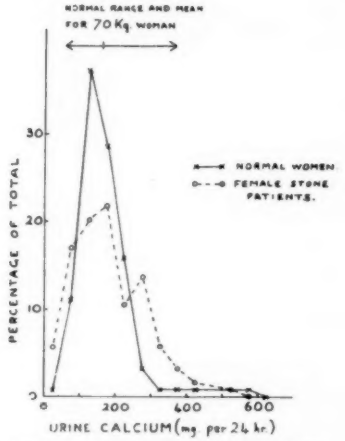

FIG. 11B.—Distribution of urine calcium values for normal women compared with a group of 124 female stone patients.

Fig. 11B shows the distribution of urine calcium values of normal women compared with those of 124 female stone patients. Once again there is a shift to the right in the stone patients showing an incidence of hypercalciuria, but this is not so marked as in the men. In fact 25% of the women with stone had values of urinary calcium higher than 250 mg. compared with 6% of normal women.

*Calcium excretion and impaired renal function.*—Stone patients with marked impairment of renal function had a low excretion of urinary calcium. When the urinary calcium is plotted against urea clearance, in no case was it found that the urine calcium was high when the urea clearance was low. Fig. 12 shows the relationship between urinary calcium

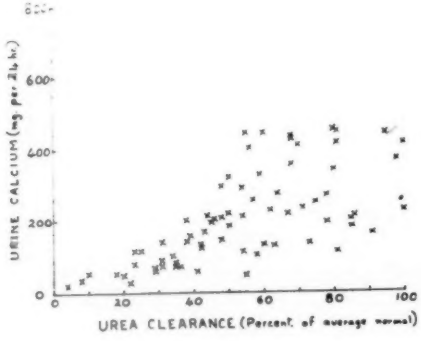

FIG. 12.—Relationship between urinary calcium excretion and urea clearance in 72 renal stone patients on a normal diet.

excretion and urea clearance for 72 patients on a normal diet. If the cases having poor renal function are omitted from the series, then it is found that the incidence of hypercalciuria is rather higher, namely 37% in the case of men stone-formers and 31% in the case of female stone-formers.

*Calcium excretion and type of stone.*—The incidence of urinary excretion of calcium and hypercalciuria was then compared with the type of renal stone (Table II). The incidence

TABLE II.—THE RELATIONSHIP BETWEEN THE URINARY EXCRETION OF CALCIUM AND THE TYPE OF STONE

| Group | Total No. of individuals | Percentage with urine calcium values greater than 200 mg. per day |
|---|---|---|
| Normal adults .. .. | 258 (56) | 26% (31%) |
| Calcium phosphate stones.. | 14 (11) | 30% (54%) |
| Calcium oxalate stones .. | 46 (26) | 53% (69%) |
| Mixed calcium oxalate and calcium phosphate stones | 53 (15) | 77% (93%) |
| Mixed struvite and calcium phosphate stones | 17 | 17% |

(Figures in brackets—Cottet and Vittu, 1955)

in the series is compared with that in a similar group of 52 calcium stone cases analysed by Cottet and Vittu (1955). It was found that the incidence of high urine calcium values was greatest in the mixed calcium oxalate—calcium phosphate calculi and almost as great in the pure calcium oxalate stones; hypercalciuria had the lowest incidence in cases composed of mixed magnesium ammonium phosphate and calcium phosphate; in the case of pure calcium phosphate calculi, the figures are intermediate, and in the last two groups most of the stones are the result of infection.

The findings agree with those of Cottet and Vittu (1955) but the incidence of high calcium values in each group in the series is lower than in the corresponding group reported in their series; and even when cases of impaired renal function in the series are omitted the figures of hypercalciuria are still lower than those of Cottet and Vittu.

Thus 66% of patients with calcium oxalate or mixed calcium oxalate—phosphate stones had average urine calcium values greater than 200 mg. per day compared with 26% of normal individuals. It is suggested, therefore, that in this group of cases of stone, hypercalciuria is an important contributory factor.

*Phosphorus excretion in normal individuals and in stone patients on a normal diet.*—The daily excretion of inorganic phosphate in healthy adults averages 800 mg. though there is a considerable variation above and below this value. The urinary excretion of inorganic phosphate is influenced by the dietary intake of phosphorus (though other factors also play a part) and it was estimated that an intake of phosphorus on the normal ward diet is within the range 1,100 ±300 mg. per twenty-four hours, which corresponds to a variation in the urinary excretion of inorganic phosphate of ±11%.

The distribution of the urinary phosphate per twenty-four hours, for 92 normal men and 118 normal women, on phosphorus intakes within the range of 1,100 ±400 mg. per day, is shown in Fig. 13 (Hodgkinson and Pyrah, 1958), the numbers of the cases being

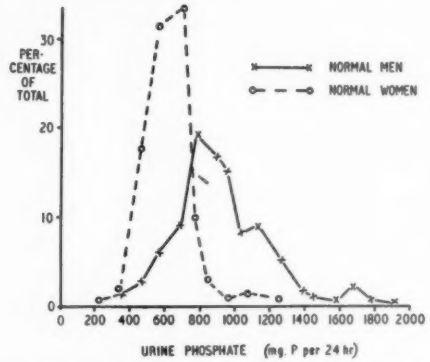

FIG. 13.—Urinary excretion of inorganic phosphate for 92 normal men and 118 normal women.

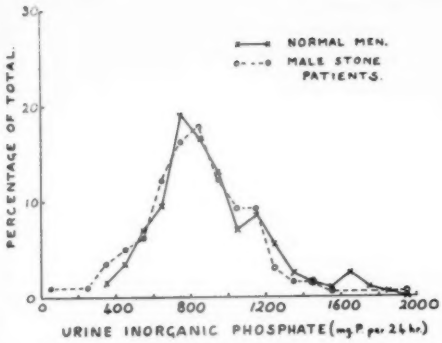

FIG. 14A.—Distribution of urinary phosphate for normal men compared with that for 198 renal stone male patients on normal ward diet.

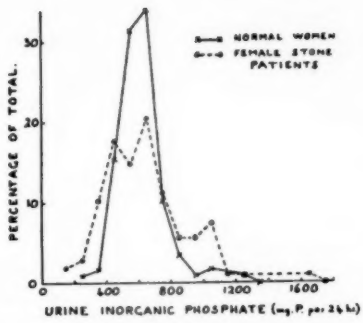

FIG. 14B.—Distribution of urinary phosphate for normal women compared with that for 108 female stone patients on a normal ward diet.

shown as a percentage of the total. The distribution of urine phosphate values for normal men varies between the figures of 450 and 1,600 mg. per twenty-four hours and thus differs significantly from that for normal women which varies between 350 and 950 mg. per twenty-four hours; so that in comparing the excretion in normal adults and in stone patients, allowances should be made for differences of sex.

Fig. 14A shows the distribution of urinary phosphate values for normal men compared with the distribution for 198 male patients with renal stones; the number of cases is again expressed as a percentage of the total. There is no significant difference in the phosphate excretion in the normal patients and in the stone patients.

Fig. 14B shows the distributions of urinary phosphate for normal women and for 108 female stone patients on a normal ward diet. A few of the female stone patients appear to have abnormally high values; thus 17 female stone patients (15·7%) had urine phosphate values greater than 900 mg. per day compared with 3·4% of the normal women. In 11 of these 17 patients the high phosphate excretion was associated with high calcium excretion and 4 of these had high or moderately high serum calcium values. One of them had, in fact, a parathyroid adenoma and the others are under continuous observation as possible cases of primary hyperparathyroidism.

The following points, therefore, have emerged from this investigation. The incidence of high urinary calcium excretion is appreciably greater in stone patients than in normal individuals and in men than in women. The incidence of hypercalciuria is greatest (60%) in cases of the aseptic calcium oxalate and the mixed calcium oxalate and phosphate stones. A high urinary excretion of calcium is not, however, found in *all* stone patients notably in those whose stones result from infection. A high urinary excretion of calcium is not *restricted* to patients with calcium stone since approximately 8% of normal adults were found to have urinary calcium values greater than 300 mg. for men and 250 mg. per day for women, whereas the incidence of calcium stones of renal origin in the general population is probably less than 0·2%. The evidence, however, suggests that the hypercalciuria is of ætiological importance for many renal calculi. Hyperphosphaturia does not appear to be a factor in the formation of calcium stones.

### Possible Causes of Hypercalciuria

If, then, hypercalciuria has an ætiological significance, we must search for the causes, but so far none has been found to explain the majority of cases. A few are the result of hyperparathyroidism, but such cases are usually diagnosed because of the raised serum calcium.

Some possible explanations of the hypercalciuria may be:

(1) That there is a high intake of calcium in the diet accompanied by a high absorption and a high urinary excretion of calcium. If, however, these hypercalciuric patients are placed on a low calcium diet, they still excrete a large amount of calcium. If increased absorption is due to sensitivity to vitamin D, it should be possible to reduce calcium absorption and therefore excretion by giving cortisone (Anderson *et al.*, 1954); in the cases, however, that have so far been submitted to this test, cortisone does not result in any reduction of calcium excretion, in fact, there may even be an increase.

(2) There may be a renal tubular defect in that calcium which is passed down the tubules in the glomerular filtrate is not reabsorbed in normal quantities by the tubular epithelium. Although Albright and Reifenstein (1948) postulated that in one group of cases of idiopathic hypercalciuria a mild infective pyelonephritis caused by the *Staphylococcus albus* had resulted in tubular damage, with resulting impairment of the calcium-reabsorption mechanism, we have not ourselves so far found much clear evidence of an infective origin of the hypercalciuria. If there is damage to the enzyme system responsible for the reabsorption of calcium by the tubules, it is possible that other tubular functions are also damaged, and we have some evidence to support this view, and it is under active investigation.

(3) The third working hypothesis is that there is some abnormal form of calcium in the blood which is excreted from the blood stream by way of the glomerular filtrate and with which the renal tubules cannot deal; the calcium, therefore, passes into the urine in abnormally high amounts. Thus, if calcium is bound to citrate or to another organic acid in excessive amounts, the tubules may not be able to reabsorb it. In such cases the urine might be expected to contain an excess of the organic radical to which the calcium is bound. This possibility is under investigation.

It is impossible here to go into greater detail either in regard to the fundamental cause of the hypercalciuria, or even in assessment of the clinical diagnosis of such cases; the following case illustrates the difficulties with our present available resources:

*Case report.—A. W.*, a man aged 48, had a nephrolithotomy for the removal of an oxalate calculus in 1953; recurrent stones were found in 1954 and these are still present. He was then found to have marked hypercalciuria.

The blood chemistry has been investigated thirty-two times since 1953, the only abnormalities found being a moderately elevated alkaline phosphatase (10 to 18 King-Armstrong units), and a slightly raised serum calcium (10·5 to 11·0 mg. %). We considered the possibility that the moderately elevated serum calcium level and the excessive urinary excretion of calcium (600 to 800 mg. per day) might be due to *multiple myeloma* but there were no bone changes, no Bence-Jones protein in the urine and no abnormality in the serum proteins.

A moderate glycosuria was found, but Cushing's disease was excluded on clinical grounds and also because the glucose tolerance curve was found to be normal and it seemed probable that the glycosuria was renal in origin.

Calcium, phosphorus, and nitrogen balance studies were carried out in 1955 (Fig. 15A). On a low calcium diet the patient was in marked negative calcium balance, the urine calcium averaging

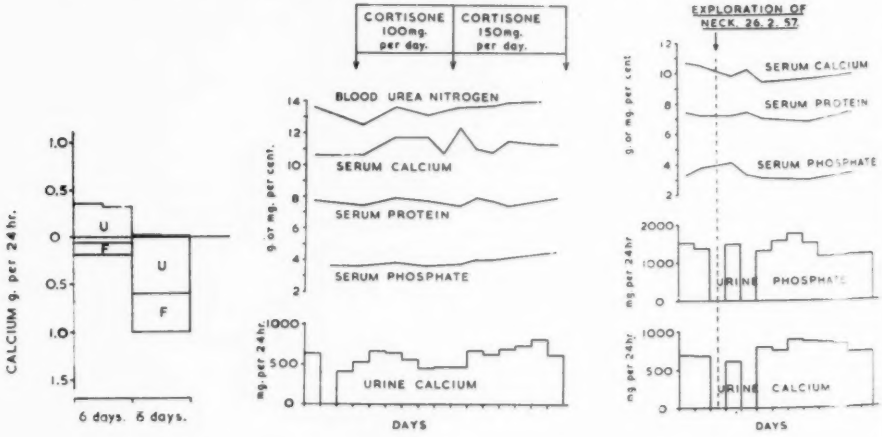

FIG. 15 (Case A. W.).—A, Calcium balance study on low and normal calcium intake. F=faeces. U=urine. B, effect of cortisone on serum calcium and urine calcium showing biochemical changes in the urine (for full explanation *see* text). C, Blood chemistry.

400 mg. per day compared with normal values of 100 to 150 mg. per day. On a normal calcium intake (1,000 mg. per day) however, the patient was in balance. The ratio of urinary to faecal calcium was greater than normal which suggests that the patient is able to maintain himself in balance on a normal calcium intake by absorbing a greater proportion of the dietary calcium than is usual, hence the absence of bone decalcification.

Is it possible that an excessive absorption of calcium from the gut is the primary defect? Anderson *et al.* (1954) and Henneman *et al.* (1956) have shown that in sarcoidosis, which

occasionally leads to renal stone formation, hypercalcæmia and hypercalciuria are due to excessive intestinal absorption of calcium, the condition resembling hypervitaminosis D. In such cases treatment with cortisone, 100 to 150 mg. per day for one to two weeks reverses this excessive absorption and results in a decrease in the intestinal absorption of calcium and a reduction in the serum and urine calcium levels. In the present case, treatment with cortisone, 100 mg. per day for six days followed by 150 mg. for a further seven days, resulted in a slight rise in both the serum and urine calcium levels (Fig. 15B). It was concluded from this investigation that excessive intestinal absorption of calcium from any cause is not the primary defect in this case; sarcoidosis as a diagnosis also appeared to be excluded.

An increase in the serum calcium level may occur when cortisone is given to patients with primary hyperparathyroidism and the possibility of parathyroid adenoma was considered. The serum calcium level of this patient varied within the range of 10·5 to 11·0 mg.% (Fig. 15C). Until recently we had considered this to be a high normal value but Keating (1955) in reporting the Mayo Clinic findings, has described many cases of primary hyperparathyroidism with average serum calcium values within this range; it was therefore decided to explore the neck for a possible parathyroid adenoma, which was done in February of this year. No evidence of parathyroid adenoma or hypertrophy was found. Following the operation the serum calcium level fell to 9·5 mg.%, but the urine calcium remained high at about 800 mg. daily. It was concluded that this is probably *not* a case of primary hyperparathyroidism although one must bear in mind the considerable difficulty which the surgeon has in locating the very smallest parathyroid adenoma.

On the evidence so far obtained this case would appear to be a true case of idiopathic hypercalciuria.

## Crystallography

Turning now to the stone itself, crystallographic methods of study have enabled its mineralogical nature and its structure and mode of growth to be studied in about 400 cases of renal calculi. The techniques used have been those of X-ray diffraction, the polarizing microscope, studies of thin sections, and microradiography. The composition of calculi using similar methods has been previously investigated by Jensen (1938, 1940, 1941), Prien and Frondel (1947) and Prien (1949), Carlstrom (1955) and Lagergren (1956).

(1) *X-ray analysis.*—By irradiating finely powdered, crystalline material prepared from different parts of the stone, with a beam of monochromatic X-rays, the rays diffracted from the intra-atomic planes of the crystal lattice can be recorded upon a photographic film as a series of lines of variable spacing and intensity, producing a powder pattern which is distinctive for each crystalline substance. This method has enabled it to be shown that there are two different types of oxalate. Chemically the two oxalates are calcium oxalate monohydrate (whewellite) and calcium oxalate dihydrate (weddellite).

Calcium phosphate occurs in three forms which can be distinguished by this technique, namely calcium hydrogen phosphate dihydrate, tricalcium phosphate and apatite (a complex phosphate probably with adsorbed carbonate). The common triple phosphate is magnesium ammonium phosphate hexahydrate or struvite.

(2) *Polarizing microscope.*—A few particles of finely powdered samples of different parts of the calculi (the nucleus or the various layers) are immersed in a liquid of known refractive index under a cover slip, and a comparison is made between the two refractive indices for the purpose of identification. This is the most sensitive method for the study of small amounts of crystalline material.

(3) *Thin-section techniques.*—A thin-section technique has been used for the study of 96 cases of stone. The stone is first embedded in Perspex (methyl methacrylate); various other resins have also been tried; part of the stone is cut away and the flat cut surface is secured to a glass slide. The opposite pole of the stone is then cut or filed away until a section the thickness of 10$\mu$ is obtained which is then examined through the polarizing microscope.

(4) *Micro-radiography.*—Using the techniques of micro-radiography of thin sections of stones, 25 cases have so far been examined and this study is continuing. Different components of the stones will absorb the rays in different proportions and these differences are recorded on the film.

*Calcium oxalate calculi.*—Their crystallographic structure has been found to be of two types, in which the habits of the crystals differ, suggesting that the calculi are formed by two different mechanisms. In Type I, the stone, which is composed of calcium oxalate monohydrate (whewellite) only, has a nodular surface; the fractured surface often shows that the stone has a laminated structure, the laminæ being upwards of 1 $\mu$ thick; radial striation is characteristic. This type of stone is believed to have been formed by crystals deposited in a colloid matrix, the slow diffusion of ions taking place to form the needle-like crystals which grow out from the centre (Fig. 16).

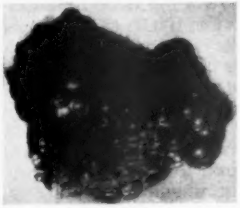

FIG. 17A.

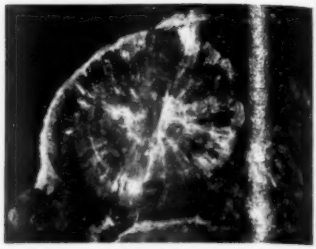

FIG. 17B.

FIG. 16.—Calcium oxalate stone (Type I). The structure is determined by colloid. The stone has a nodular surface and cross section shows lamination and radial striation.

FIG. 17A.—Calcium oxalate stone (Type I), magnified, showing nodular surface.

FIG. 17B.—Fractured surface showing radial striation and lamination.

FIG. 18.

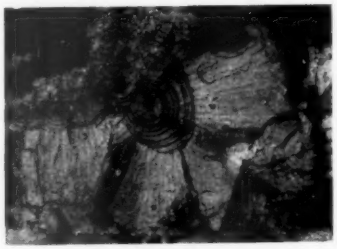

FIG. 19.

FIG. 18.—Thin section of nodular calcium oxalate stone (Type I). There is well-marked lamination and radial striation. ×15.

FIG. 19.—Calcium oxalate monohydrate stone (Type I). There is radial striation from the centre to the periphery. The lamination is limited to the central part of the stone. ×15.

Fig. 17A shows a stone having the characteristic nodular surface of a Type I oxalate stone. Fig. 17B shows the fractured surface revealing both the lamination and the radial striation. Fig. 18 is a thin section of a Type I stone; the centre is a mass of crystals of calcium monohydrate which were originally dihydrate; the characteristic radial striation and the lamination is shown. The dark lines between the laminæ represent the colloid matrix.

Fig. 19 (Type I stone) shows a laminated nucleus of calcium oxalate monohydrate (whewellite), of which the entire stone is composed. There is radial striation which is characteristic of the type of stone from the centre to the extreme periphery, so there is no interruption in the fundamental structure of the calculus; the striation is due to long acicular crystals growing close together, disposed radially. The colloid in the centre is concentrated in the dark rings. The lamination here is unusual, since it usually extends throughout the entire stone.

In Type II oxalate calculi the crystallographic appearances are different from those in Type I. Here, there is either a disorganized mass of calcium oxalate dihydrate (weddellite) crystals alone; or the interstices between the dihydrate crystals are filled with colloid, or with calcium phosphate (apatite) and colloid; or such a stone serves as a nucleus for a further deposition of a laminated zone, the layers alternating between apatite (calcium phosphate) and calcium oxalate dihydrate. The appearances of these stones with their perfectly normal crystals and no embedding colloidal mass, suggest that the dihydrate has been formed by a primary crystallization process and not by secondary crystallization in a gel or by passing through an intermediate colloidal phase. The stone itself has a coarse or a fine crystalline surface, with the crystals also visible on the fractured surface; radial striation is absent and the fine lamination of the monohydrate stone is also absent; sometimes there is rough layering (Fig. 20).

Fig. 21A shows the typical crystalline surface of a Type II stone. Fig. 21B shows the fractured surface; the white patches are layers of apatite which appear powdery; the rest of the stone is composed of colourless or yellowish crystals of dihydrate (weddellite); the rather crude layering indicates stages of growth in the stone.

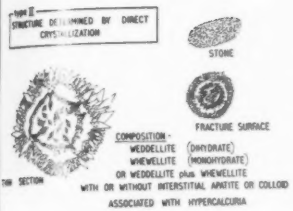

FIG. 20.

FIG. 21A.

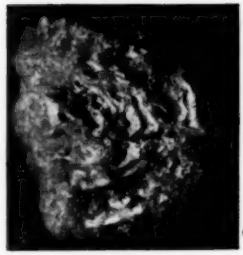

FIG. 21B.

FIG. 20.—Calcium oxalate stone (Type II). The structure is determined by crystallization. The surface is highly crystalline. The fractured surface is also crystalline. There is rough layering rather than well-marked laminations and there is no radial striation.

FIG. 21A.—Calcium oxalate stone (Type II). The surface is highly crystalline.

FIG. 21B.—The fractured surface shows crude layering. The white patches are apatite (calcium phosphate).

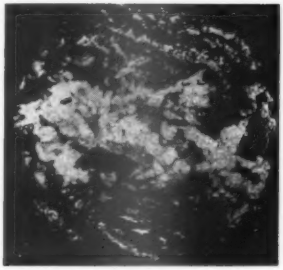

FIG. 22A.

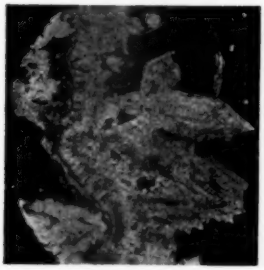

FIG. 22B.

FIG. 22A.—Thin section of calcium oxalate stone (Type II). (For description *see* text.)

FIG. 22B.—Thin section of calcium oxalate stone (Type II) showing much crystallization by calcium oxalate dihydrate. On the surface of the stone (right of the picture) lines parallel to the edge represent growth lines in the crystallization.

Fig. 22A shows an example of a Type II stone, namely a mixed calcium oxalate dihydrate and apatite stone (weddellite type). The crystals in the right centre of the field were large calcium oxalate dihydrate (weddellite) crystals, which have undergone recrystallization into the much smaller crystals of calcium oxalate monohydrate (whewellite). It is possible that the whole of the centre area in the field has been one large crystal of the dihydrate (weddellite) which has subsequently undergone recrystallization into monohydrate. The black parts in the field are again either colloid or apatite or a mixture of both. The small crystals in the upper and lower part of the field are of the monohydrate (whewellite).

The single crystals of the dihydrate (weddellite) are often especially obvious at the surface of these Type II calcium-oxalate-containing stones. The large crystals show lines which indicate their growth. The black part is either colloid or apatite (calcium phosphate) or a mixture of both (Fig. 22B).

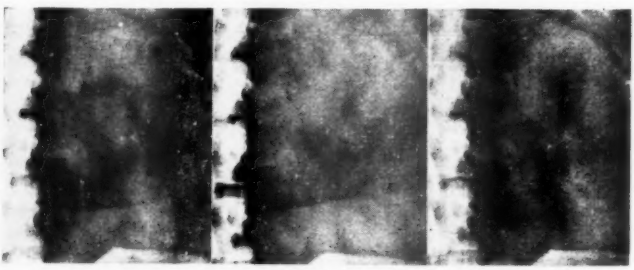
If it is true that the Type II stones have been formed by primary crystallization, one would expect them to be associated with a high concentration in the urine of the stone-forming material. It has been found, in fact, that stones of this group are associated with hypercalciuria.

It is thought, therefore, that there are two types of calcium oxalate stone which are recognizable because of their structure by crystallographic techniques and which are probably aetiologically distinct. In the Type I stones it is suggested that the structure of the stone has been determined by the colloid; and that the incidence of hypercalciuria is no greater than in normal people. In this group, investigations into the urinary colloids may repay further study. In the Type II cases in which the structure of the stone appears to have been determined by direct crystallization, it has been found that the incidence of hypercalciuria is high, suggesting, in fact, that it is of aetiological importance.

FIG. 23.—Calcium phosphate stone showing fractured surface of calcium phosphate and magnesium ammonium phosphate hexahydrate. ×2.

FIG. 24.—Thin section of a struvite stone (magnesium ammonium phosphate hexahydrate). (For description *see* text.) ×3·5.

*Calcium phosphate calculi.*—Fig. 23 is a stone (cut across) composed of calcium phosphate (apatite) and magnesium ammonium phosphate hexahydrate (struvite).



The structure of a phosphate stone is shown by the thin section of a struvite stone (Fig. 24). When the thin section is examined under polarized light, the stone has a laminated structure, with comparatively large single crystals of magnesium ammonium phosphate hexahydrate (struvite) arranged in rows along each band, the crystals being embedded in colloid or in apatite. The appearances suggest that each layer was deposited in the manner described by Schade, namely the primary formation of a nucleus followed by the deposition of successive layers of colloid, with crystal deposits in each layer.

## PREVENTION OF STONE FORMATION

The principles that have been used for the prevention of stone have been firstly to try to provide physical conditions in the urine either by methods of dilution or by alterations of the pH, which will make it unlikely that the stone-forming substances will be precipitated. An alternative method is to deny access to the urine of stone-forming substances such as phosphorus and calcium.

It is, however, interesting to refer to what actually happens in badly functioning kidneys if a stone-forming substance such as calcium is denied normal access to the urine because of poor renal function, and alternatively what happens if a good deal of calcium is presented to such a kidney simply because it happens to be in the blood stream.

Fig. 25 shows two small calcium-containing calculi inadvertently left behind at operation

23.6.48. 8.1.53. 9.9.54.

FIG. 25.—Two small calculous particles left behind at operation in a very badly functioning kidney. The stone disappeared without further interference (*see* text).

in a patient who had only one badly functioning kidney which was also infected with *Bacillus proteus*; in spite of the infection the stones were no longer visible radiologically when the patient was X-rayed three years later; they had probably undergone dissolution. The urinary excretion of calcium here was very small.

Similarly renal calculi never occur in kidneys which are the seat of chronic nephritis (unless, of course, the calculus has ante-dated the nephritis), because of the inability of the diseased kidneys to allow calcium to pass into the urine in any quantity. On the other hand, if in a patient who has advanced glomerulonephritis, large amounts of calcium are absorbed from the gut into the blood stream following, say, a very high intake of milk

calcium salts may be deposited in the glomeruli producing a stippled type of calcification throughout the entire parenchyma of the kidneys (Fig. 26); and also in such cases the excess

FIG. 26.—Bilateral calcification in both kidneys in a case of glomerulonephritis. The patient had had a high intake of calcium by mouth for a prolonged period. (By kind permission of Dr. Sosman, Peter Bent Brigham Hospital, Boston, U.S.A.)

of calcium salts may be deposited in subcutaneous and peri-articular tissues in an attempt to prevent the elevation of the serum calcium.

This summary will refer, briefly, to the ancillary methods which are being tried out to prevent the recurrence of calcium-containing renal calculi.

(1) *High intake of fluids.*—It is always advised that the stone-former should have an appreciably higher daily intake of fluids than a normal individual; apart from cystine stones (Dent, 1955), however, it is doubtful if sufficient urine volume can be achieved to obtain dissolution of existing calculi, though fluid may prevent the growth of crystalline matter into stones. An extreme example of the effect of a very high intake of fluids in the rat was shown by a simple experiment by Grove *et al.* (1950); these workers were able to induce bladder stones in rats by implanting tiny pieces of zinc through a suprapubic cystotomy; by substituting a solution of glucose for tap water for drinking which, by inducing thirst, caused a very high total daily intake of fluid, stones were prevented from forming around the zinc implants, and one-third of pre-formed calculi underwent dissolution.

(2) *Diet control: acidogenic diet.*—Higgins (1943) advocated an acid-ash diet to try to reduce the recurrence rate of renal calculi following operation. If the urinary pH is reduced, however, the increase in the urinary calcium which results may neutralize or outweigh any favourable effect from the change in pH. Moreover the urinary calcium salts do not differ in their solubility with the available range of pH to the same extent as do cystine and uric acid, so that the change in pH cannot be expected to give remarkable results.

In the case of some soft, non-infected, recumbency calculi consisting of almost pure calcium phosphate and a minimum of colloid (which are uncommon), the administration of ammonium chloride in biggish doses to render the urine acid, with or without an acidogenic diet, may effect a complete disintegration or dissolution of the calculi. A similar dissolution of soft phosphatic renal stones in certain cases of hyperparathyroidism with advanced skeletal changes, has been obtained; and such a treatment is the most reliable method of dealing with severe cases of phosphatic incrustation of the bladder.

(3) *Calcium excretion.*—Henneman *et al.* (1956) proposed the use of phytic acid (inositol phosphoric acid) for reducing urinary calcium excretion in sarcoidosis, in which the hypercalciuria is probably due to the excessive absorption of calcium from the intestine (Anderson *et al.*, 1954), and they suggested that this compound might be of value in the treatment of idiopathic hypercalciuria. In idiopathic hypercalciuria, however, it would appear that the defect differs from that in renal sarcoidosis in that it is renal rather than intestinal, so that the use of phytic acid in that condition would be of limited value.

(4) *Phosphate excretion.*—It has already been shown that in normal individuals and in stone patients the urinary excretion of phosphate is usually within normal limits. It is possible, however, that a reduction of the urinary phosphate may be of value in the treatment of recurrent calcium phosphate stone and the use of aluminium hydroxide gels is being recommended in suitable cases. This treatment can be used so as to cause an appreciable reduction in urinary phosphate by precipitating phosphate in the gut, but we find that it is sometimes accompanied by an increase in urinary calcium which is undesirable.

Various preparations of aluminium hydroxide are available (Pyrah and Smith, 1956) and the use of Hyalgel, which has the highest content of aluminium hydroxide with adsorbed carbonate has been preferred. This preparation is best used for the treatment of calcium-phosphate stones and probably it is not indicated with oxalate calculi. There has been

difficulty in inducing patients to stay on this treatment for long periods of time. Moreover it has not been certain that the treatment is of permanent value when there is a persisting urinary infection which cannot be cured. There has been a tendency, therefore, to limit the use of this treatment to co-operative patients in whom the urinary tract is free from infection and who also can attend hospital for adequate supervision.

Fair success has been achieved in reducing the phosphaturia. It is essential that the Hyalgel be given with meals in order to produce the maximum reduction of the urinary phosphate. It is also necessary for frequent tests on twenty-four-hour specimens of urine for phosphorus to be made. Fig. 27 shows the measure of reduction in urinary phosphate

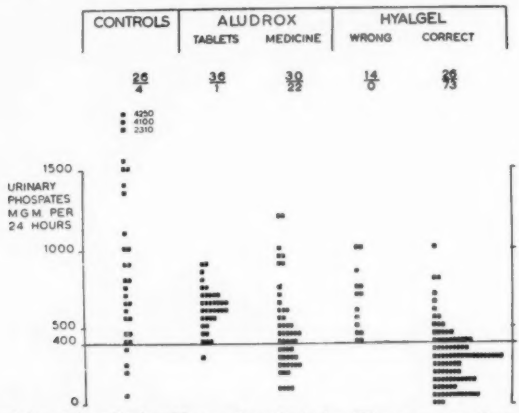


FIG. 27.—Effect of aluminium hydroxide on phosphaturia. The amounts of phosphate in the urine (mg./twenty-four hours) of 25 patients with renal stone while taking a normal diet with various preparations of aluminium hydroxide. 232 tests are each represented by one small square. Column 1, no aluminium therapy; column 2, Aludrox tablets; column 3, Aludrox medicine; column 4, Hyalgel taken inadequately or not with meals; column 5, Hyalgel 30 ml. q.i.d. with meals. 400 mg./twenty-four hours considered satisfactory, fractions represent the proportions of unsatisfactory to satisfactory results.

which can be achieved, and it has been found that Hyalgel is much better in this regard than Aludrox in doses which patients will tolerate.

Of 9 patients treated for periods of one and a half to three and a half years under what are regarded as optimum conditions, the clinical histories are as follows: These 9 patients between them have had 24 operations for stone; they had voided between them at least nineteen other stones. 3 patients had had nephrectomy and 4 had had partial nephrectomy. During the period of treatment one stone diminished markedly in size. Only one new stone has appeared in the 9 patients and this occurred during a period when treatment was not controlled; no existing stone has increased in size. The treatment, therefore, in a small group of patients, with the provisos that have been mentioned, is worth while, provided the criteria mentioned are also observed.

(5) *Oxalic acid excretion.*—Because of the lack of a suitable method for estimating oxalic acid in urine, few studies have been made of oxalic acid excretion in stone patients. A method has been recently developed which is considered to be sufficiently sensitive and specific. It has been found that urinary oxalic acid excretion is generally within normal limits in stone patients but that it may be slightly raised in patients with pure calcium oxalate stone. It is possible, therefore, that a reduction in the urinary excretion of oxalic acid may be of benefit in such cases; we have not yet tried this approach. Archer *et al.* (1957) described a case of hyperoxaluria in which there were 200 mg./day oxalic acid excreted in the urine (the normal figures being about 20 mg./day) and they reported that oxalic acid excretion could be reduced by feeding benzoic acid; the condition appears to be rare.

(6) *Excretion of organic acids:* (*a*) *Glucuronic acid.*—It is well recognized that, for reasons which are only partly understood, biological fluids including urine have a greater ability than water to hold calcium salts in solution. Mandl *et al.* (1953) emphasized the importance of organic acids in this process and Prien and Walker (1955) suggested that the ability of urine to hold calcium salts in solution might be enhanced by increasing the urinary excretion of glucuronic acid by the ingestion of salicylic acid. Trials in cases of recurrent stone have, however, shown that there is no significant reduction in recurrence rate when the excretion of glucuronic acid is thus increased (Vermeulen *et al.*, 1957).

(*b*) *Citric acid.*—Citric acid, which is excreted in the urine in amounts varying from 400 to 1,000 mg. per day, is one of the organic acids which probably plays an important part in helping to maintain calcium salts in solution. The excretion of citric acid is reduced in many cases of renal stone, and Shorr (1945) proposed the use of œstrogens to increase the urinary excretion of this acid. Conway *et al.* (1949) thought that the reduced excretion of citric acid could be explained by the presence of a urinary infection in these cases, but probably the infection does not account for all the low values which are found and further studies are being carried out on this aspect of the problem.

(7) *Calgon.*—The possibility of using the water-softener Calgon (sodium hexametaphosphate) as a therapeutic agent in the treatment of stone has been studied in our department (Care and Wilson, 1956). Calgon has the property of forming a soluble complex with calcium by an ion exchange process, and it was found that the experimental formation of stones in rats could be prevented by the addition of small quantities of Calgon to the drinking water. The suppression of stone formation was, however, accompanied by slight calcification in the renal parenchyma which was clearly undesirable. It may be possible to prevent this by using lower concentrations of Calgon and further long-term trials are proposed.

(8) *Chelating agents.*—Chelating agents are able to form complexes with various metals including calcium, and it is thought that this process may play a part in the formation or prevention of stones. Whereas in the case of phytic acid, citric acid, and Calgon, the combination with calcium involves an exchange of ions or the formation of a salt, chelation involves the formation of a ring structure with co-ordination linkages. The compound ethylene diamine tetra-acetic acid (E.D.T.A.) is a typical chelating agent commonly used for the decalcification of tissues *in vitro*. McGeown and Bull (1957) suggested that some of the urinary amino-acids may hold calcium in solution by forming soluble chelates, and reported that the urinary excretion of amino-acids is reduced in some stone patients. It is possible, therefore, that beneficial results might be obtained in some cases by increasing the urinary excretion of amino-acids if that is found to be possible.

ACKNOWLEDGMENTS.—The author desires to acknowledge the help and co-operation received from Dr. C. K. Anderson, Dr. A. Hodgkinson, Mr. B. T. Murphy and Mr. M. J. Purton.

# Inability to take aspirin . . .

IT HAS BEEN reported (*Brit. med. J.*, 1 : 444, 1957) that of 178 rheumatic patients, 25% could not take plain aspirin in adequate dosage.

Of this 25%, however, the great majority tolerated a modified aspirin such as Paynocil.

Not only are Paynocil tablets usually well tolerated by the stomach (even on the heavy dosage needed for rheumatoid arthritis), but they are extremely palatable, disintegrate instantly on the tongue without water, and cause no discomfort or unpleasant after-sensation.

## . . . indicates PAYNOCIL

## The Physiological Control of Aldosterone Secretion [*Abridged*]

By FREDERIC C. BARTTER, M.D.

*National Heart Institute, Bethesda, Md., U.S.A.*

I SHALL not attempt to review all the work that has been done on the control of aldosterone secretion: rather, I shall undertake the much easier task of summarizing our own studies over the past three years.

The method we have used for assay of urinary aldosterone is that of Liddle and associates (1955). This is a bio-assay method, using adrenalectomized dogs on a constant, high sodium diet. The steroid is given intravenously, and the index of activity is a weighed sum of the sodium retention and the potassium loss in the second and third subsequent hours. This index is linear with log-dose over a 32-fold dose range, with a "lambda" for the assay of 0·24. It was shown that cortisone and hydrocortisone, in quantities many times those that could appear in a day's urine, do not materially affect the assay, and so methylene chloride extracts were usually washed but not chromatographed. In the studies with ACTH and cortisone, however, a preliminary extraction with ether was done to remove hydrocortisone.

We have studied the effects of three variables on aldosterone secretion: circulating ACTH, total body potassium, and body fluid volume.

Circulating ACTH was increased by giving large doses of ACTH gel intramuscularly to normal subjects on balance regimens. In all cases aldosterone excretion rose to two to four times control levels. If the ACTH was continued, however, aldosterone excretion fell in a few days to below control levels, and this occurred even when sodium intake was so low as to prevent any retention with ACTH. Circulating ACTH was suppressed with large doses of cortisone and hydrocortisone without appreciable effect on aldosterone excretion. These findings supported observations showing normal aldosterone secretion by patients with hypopituitarism to suggest that ACTH is not necessary, and probably not of great physiological importance, in the control of aldosterone secretion.

Total body potassium was increased by giving large potassium "loads", and decreased by giving low potassium diets, with and without cation exchange resins, to normal subjects on balance regimens. Serum potassium rose and fell with gains and losses of total body potassium in all instances. The potassium "loading" consistently increased aldosterone excretion to about two times control levels, and the potassium depletion consistently decreased it to less than half control levels. The effect of "loading" was present even when extra sodium was given to replace that excreted in response to potassium salts; the effect of depletion was present even on a diet so low in sodium that none could be retained in response to potassium loss.

Despite the consistency of the potassium effects, the relatively small magnitude of the changes in aldosterone secretion despite very large changes in potassium intake suggests that they are not of primary importance in the physiological control of aldosterone secretion.

Changes in body fluid volume were induced experimentally by (*a*) changing total body water volume with dehydration and over-hydration; (*b*) changing extracellular fluid volume with sodium deprivation and sodium "loading"; and (*c*) changing intravascular volume with phlebotomies, and infusion of red cells or of albumin. All subjects were studied under metabolic regimen.

(*a*) *Total body* fluid volume was decreased by depriving normal subjects of water and subjects with diabetes insipidus of pitressin while limiting water intake; aldosterone secretion consistently rose despite moderate to marked hypernatræmia. Total body fluid volume was increased by giving water to normal subjects receiving pitressin tannate in oil to prevent diuresis: aldosterone secretion consistently fell despite marked hyponatræmia.

(*b*) *Extracellular* fluid volume was decreased by depriving normal subjects of sodium, with and without use of mercurial diuretics: aldosterone secretion consistently rose. Volume for volume, the increases in aldosterone secretion were much larger than those induced by deprivation of water alone.

*Extracellular* fluid volume was increased by giving dietary salt or "physiologic" saline infusions to sodium-depleted normal subjects: aldosterone secretion consistently fell. *Extracellular* fluid volume was increased with simultaneous contraction of intracellular fluid volume by infusing hypertonic saline into sodium- and water-depleted normal subjects: aldosterone secretion again consistently fell.

The increase of aldosterone secretion with sodium depletion could be produced during potassium depletion (with falling serum potassium), and the decrease with water or saline "loading" could be produced despite simultaneous potassium "loading" (with rising serum potassium). Thus the "volume" effects were not secondary to effects on potassium metabolism.

(*c*) *Intravascular* volume was decreased by performing phlebotomies on normal subjects, with simultaneous administration of saline to prevent any net sodium loss: aldosterone secretion consistently rose. If several days were then allowed to elapse, aldosterone secretion spontaneously fell as hæmodilution ensued.

*Intravascular* volume was increased by reinfusion of separated red cells into the donors just described: aldosterone secretion consistently fell. *Intravascular* volume was increased by infusion of salt-poor human albumin into normal, hypoproteinæmic, and cirrhotic subjects: aldosterone secretion consistently fell. In the hypoproteinæmic patients, the fall occurred despite large diuresis of sodium and thus *contraction* of *total* extracellular fluid volume.

We have found elevated aldosterone secretion in cardiac, cirrhotic, hypoproteinæmic and nephrotic patients, despite high intakes of sodium and grossly expanded extracellular fluid volume. In all groups except the first, it is likely that intravascular volume is diminished as fluid escapes to the peritoneal cavity or interstitial spaces. In some cardiac patients, increased intravascular volumes have been reported. It may be that "effective" blood volume is compromised in such subjects despite increased total volume. On the other hand, increased aldosterone secretion and increased blood volume have not thus far been reported in the same subject.

The magnitude of the changes in aldosterone secretion with small changes in intravascular volume suggests that "volume" stimuli are of major physiological importance in the control of aldosterone secretion.

President—C. N. ARMSTRONG, M.D., F.R.C.P.

[*November* 27, 1957]

**Idiopathic Hypoparathyroidism with Thin Bones.**—H. K. IBBERTSON, M.R.C.P., M.R.A.C.P. and RUSSELL FRASER, M.D., F.R.C.P.

Mrs. M. S., aged 31. Indian.

*History.*—Chronic backache following a fall fifteen years previously. Hysterical attacks with coma and spasms of hands and feet during same period.

Thin bones and macrocytic anæmia discovered during recent (eighth) pregnancy.

*Obstetric history.*—Eight pregnancies:

| | | | |
|---|---|---|---|
| 1942 | Male, stillborn. | 1948 | Male, alive. |
| 1945 | Female, died after fifteen hours. | 1953 | Female, died after ten hours. |
| 1946 | Male, died after few hours. | 1954 | Female, died 1 year pneumonia. |
| 1947 | Male, died after few hours. | 1956 | Female, alive. |

The Wassermann reaction was found to be positive during the 5th pregnancy and a course of penicillin and arsenic given with survival of the child. Despite a negative W.R. the child of the 6th pregnancy died after ten hours.

*On examination* (*three weeks postnatal*).—Thin hysterical Indian woman. Bilateral

lenticular cataracts. Positive Trousseau sign with carpal spasm after application of the cuff for one minute. Bone tenderness.

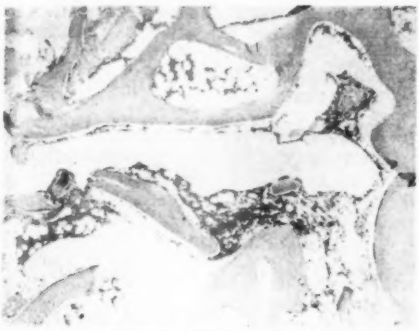

FIG. 1.—Iliac crest biopsy. Decalcified section ×50. H. and E. stain. Shows thin, widely spaced trabeculæ with normal marrow.

*Investigations.*—X-rays: Thin bones. Vertebral wedging. Intact lamina dura. No pseudo-fractures or subperiosteal erosions. Hæmatology: Blood—Hb 11·8 grams/100 ml., M.C.V. 107 cu.$\mu$. W.R. negative. Marrow megaloblastic. Folic acid absorption normal. Biochemistry: Serum calcium 6·2, phosphate 7·3 mg./100 ml. Alkaline phosphatase 5·6 K.A. units. Elsworth Howard Test: Increase in urine phosphate excretion from 10 mg./hour to 60 mg./hour following 200 units parathormone intramuscularly. No rise on control day. Normal result. Strontium infusion test: Daily deposited bone calcium. 0·6 plasma units (low value). Bone biopsy: Thin trabeculæ consistent with osteoporosis. Undecalcified section shows normal osteoid seams.

*Treatment.*—Calciferol 200,000 units daily by mouth. High calcium diet—3 grams of added calcium (as gluconate) daily.

*Progress.*—Restoration of serum biochemistry to normal with relief of bone pain and tetany. Skeletal X-rays unchanged.

*Discussion.*—The association of megaloblastic anæmia with thin bones and tetany suggested steatorrhæa, but two fat balances were normal. The anæmia responded to folic acid and did not return during eighteen months' observation. The clinical picture and therapeutic response was characteristic of megaloblastic anæmia of pregnancy.

The biochemical findings indicated hypoparathyroidism, and the Elsworth Howard test confirmed a normal renal response to parathormone. The occurrence of hypoparathyroidism with thin bones is unusual although demineralization is seen in pseudo-hypoparathyroidism (Reynolds *et al.*, 1952). Albright (1956) described a patient who developed hypoparathyroidism following thyroidectomy. Marked bone rarefaction due to osteomalacia (confirmed histologically) occurred. Rapid healing followed vitamin D therapy. A 12-year-old girl with idiopathic hypoparathyroidism and "demineralized" bones was described by Schulman and Ratner (1955). No histological confirmation was obtained but rapid radiological healing on calciferol therapy suggested osteomalacia.

In the present patient, osteoporosis rather than osteomalacia was confirmed by the characteristic bone histology, a low bone uptake of calcium shown by the strontium tracer test, and absence of radiological change despite correction of the biochemical abnormalities of hypoparathyroidism for eighteen months.

The previous history suggests reasons for the osteoporosis. The diet had been poor and contained little protein or calcium. Lactation was established after each pregnancy, the total duration of lactation being about three years. This, together with the stress of 8 pregnancies, presumably caused depletion of protein and calcium allowing osteoporosis to develop in the presence of hypoparathyroidism.

Whether the so-called "idiopathic" hypoparathyroidism was precipitated in any way by these nutritional factors or whether syphilis itself participated in its ætiology remains speculative.

*Final diagnosis.*—Healed syphilis. Idiopathic hypoparathyroidism. Osteoporosis. Megaloblastic anæmia of pregnancy.

*Comment.*—The plasma calcium and phosphorus and their response to treatment confirm the diagnosis of hypoparathyroidism. The bone biopsy clearly excludes osteomalacia and the bone rarefaction must therefore have been due to osteoporosis. This is a rare association.

**Pre-Tibial Myxœdema Following Subtotal Thyroidectomy and Recurring after Surgical Excision.**—J. H. BRIGGS, M.B. (for P. M. F. BISHOP, D.M).

Miss E. S., aged 50.

*History.*—Eleven years ago: Onset of nervousness accompanied by dyspnœa and palpitations on exertion, and considerable weight loss, but her appetite was poor and there was no preference for weather.

*On examination.*—At that time, she had exophthalmos with lid lag, a tremor of the hands which were moist and a tachycardia of 120/min. at rest. B.P. 180/80. B.M.R. +35%. A diagnosis of thyrotoxicosis was made.

Six months after onset of symptoms a subtotal thyroidectomy was performed. Six weeks after the operation swelling of the ankles was first noticed, at first variable and pitting, later persistent and non-pitting—treated with thyroid extract without effect.

Six years ago: Increasing weight, hair falling. B.P. 180/105. B.M.R. +1%. Treated with stilbœstrol implant and later with deep X-ray to the pituitary. There was some regression of the exophthalmos, due possibly to a local effect on the retro-ocular tissue.

Four years ago: A plastic operation was performed, when myxœdematous tissue and skin over the dorsum of the left foot and ankle were excised; a split skin graft from the anterior surface of the left thigh was applied and healed well.

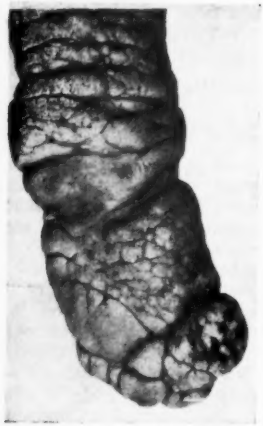

FIG. 1.—Right foot prior to excision of myxœdematous tissue.

FIG. 2.—Three years after plastic operations showing recurrence over both feet and involvement of donor area on left thigh.

Following the operation myxœdematous changes occurred in the donor area on the left thigh; four months post-operatively similar changes took place in the grafted skin on the left foot. Nevertheless the patient was satisfied with the result of the procedure and six months after the first operation, a similar operation was performed on the right foot, skin being taken from the posterior surface of the right thigh (Fig. 1). The grafted skin healed well and although subsequently myxœdematous changes developed in it, in the donor site they did not.

The condition progressed slowly for about two years and is apparently now static (Fig. 2).

X-ray of the hands shows tufting of the distal phalanges. There is no evidence of periosteal reaction over the lower tibiæ or fibulæ.

A trial of tri-iodothyronine ointment applied locally had been ineffective.

The following cases were also shown:

## Laryngology—A Retrospect, a Review and a Revaluation

### PRESIDENT'S ADDRESS

By R. J. CANN, M.S., F.R.C.S.

BEING curious as to the history of origin of this Section of Laryngology, I discovered that we are this year 50 years old—a golden jubilee—and it seemed a good moment to look back, to take stock of ourselves and, perhaps, to consider the future of our specialty.

1907 was not the beginning of a society of laryngologists in this country, but it was the year when many already existing medical and surgical associations were grouped together to form the Royal Society of Medicine. This Laryngological Section of ours was the amalgamation of two previous existing societies—the British Rhino-Laryngological Association and the London Laryngological Society. The latter was founded by Sir Felix Semon in 1893 and he became its President a year later. While his name is a household one with us, I wonder if we realize just how much, by his writings in this country and in others, by his reputation as a laryngologist and, most of all, by his personality, he helped our specialty to attain recognition and to give it stature. Semon came to London in 1875 as a young man with an introduction to Morell Mackenzie, who was the foremost laryngologist of the country and who, rightly, may be called the founder of Laryngology in this country. It was Mackenzie who started the British Rhino-Laryngological Association in 1888 and was its first President; with Norris Wolfenden a year earlier he had launched the *Journal of Laryngology* and with him shared the editorship. Even more remarkable, in 1863 Mackenzie founded his "Metropolitan Free Dispensary for Diseases of the Throat and Loss of Voice"—the first hospital devoted to diseases of the throat in the world and, of course, better known to most of you as Golden Square Hospital. Laryngology was then a very new branch of medicine and its developing into a specialty may be dated from the discovery of the laryngoscope. Mackenzie had learnt to use the laryngoscope in Budapest from Professor Czermak and within three years of returning to London had won the Jacksonian Prize of the Royal College of Surgeons with his essay on "The Pathology and Treatment of Diseases of the Larynx: the diagnostic indications to include the appearance as seen in the living person".

You will forgive me if I go just one step farther back into history, but on reading Mackenzie's book on the laryngoscope, I discovered one item of particular chronological interest. Much has been written as to who deserves the honour of discovering the laryngoscope and thus of being the founder of our specialty, but there seems little doubt that it was Czermak who recognized its practical usefulness in medicine and popularized it with the medical profession, and it was he who taught Mackenzie. Czermak had borrowed the laryngeal mirrors from Professor Türck of Vienna. Let me quote from Mackenzie's book: "In the year 1857, in the month of November, Professor Czermak, of Pesth, borrowed from Dr. Türck the little mirrors which that gentleman, in spite of the exhortation of his friends, had thrown aside as useless. In a short time, his superior genius, untiring perseverance and natural dexterity, enabled him to overcome all difficulties. Artificial light was substituted for the uncertain rays of the sun; the large ophthalmoscopic mirror of Ruete was used for concentrating the luminous rays; the awkward hinge which united the laryngeal mirror to its stem was dispensed with; and mirrors were made of different sizes. Thus it was that Czermak created the art of laryngoscopy." Did you notice the date?—November 1857. As I have said, this year is a jubilee of our Section—but this month is the centenary of the origin of our specialty.

In looking back I often wonder just what those early laryngologists were like and were able to do. They certainly had the laryngoscope, but they had no electric light, in fact, no electricity for light or cautery or suction. They had no knowledge of bacteria, no X-rays, until 1880 no cocaine and no adrenaline, and they were forced to invent most of their instruments. And yet Mackenzie wrote a textbook on disease of the throat and nose —in two volumes, each of over 500 pages—a work which was a standard for years and which Semon translated for Germany where, also, it had a long reputation. Both of these men were physicians, as were most of the early laryngologists. A notable exception was Sir Henry Butlin who, as junior of the surgeons at St. Bartholomew's, was persuaded to take on the laryngology that no one else was willing to do. Among some who were physicians to their hospitals before they were laryngologists, we remember D. R. Paterson of Cardiff and Watson-Williams of Bristol. Sometimes the apprenticeship was in general practice and notable in this group were Dundas-Grant and Dan McKenzie. But gradually the emphasis in our work became surgical, and the terms of appointment to hospital staff as "Surgeons in Charge" became the custom. More and more the specialty became a branch of surgery with curious anatomical limitations. The possession of a higher qualification in surgery became a necessity for hospital appointments. Also, in many hospitals, we became wedded to the otologists who had been a specialist surgical group for a long time previously. As a result of such a parentage it is now difficult to distinguish a laryngologist from an otologist, and it is perhaps surprising that our Sections of Laryngology and Otology still retain their identity and tradition. I am not, for one moment, suggesting it should be otherwise.

With the development of surgical work, there was a need for larger departments in hospitals with an increasing demand for beds. The supply of beds never seemed to keep pace with this increasing demand and the result was that for many years the waiting lists for throat and nose operations were among the most notorious and most ridiculous features of hospital administration. I think this problem was the cause of two interesting things. One was the development of much out-patient operative work, most of which we should now regard with horror, and the other was the overflow of much of the tonsil and adenoid surgery into the hands of other people, who became expert at this work but were not laryngologists. We are thankful that for one reason and another, the long waiting list is disappearing, or has disappeared.

I suppose I have lived through the heyday of operative assault upon the nose and sinuses and I have seen develop an appreciation of the importance of their physiology. In particular, one has learned the need for the preservation of cilial activity. Otty (1957) reviewed the changing aspect of nasal disease and surgery and commented on the value of a submucous resection of the septum. It may be that this important operation will be one of the few left in our repertoire of nasal surgery. I served some of my apprenticeship at Gray's Inn Road seeing in the out-patient department the "old cases", and among them the anatomical and physiological wreckage of the nose for which nothing more could be done. These were the result of well-intentioned surgery by many well-known seniors, but they caused one furiously to think! Nevertheless, I expect most of my generation still, at times, wish to go the other way and avoid having to look at the all too familiar nose which is waiting on the out-patient benches, pathetically faithful and hopeful, and curiously grateful.

There has been, too, a growing appreciation of the importance of the non-infective disorders of the nose and sinuses, in particular those associated with allergy and those due to psychosomatic changes. Of the latter I have been aware for a number of years but I have been shy of talking or teaching about them. You may remember a lecture by Dr. Lüscher (1954) given at the Institute of Laryngology just four years ago, when he talked of the psychological factors of ear, nose and throat diseases. I talked to him afterwards and thanked him for saying so much of what I believed, and I was interested to hear him say how much courage he had needed to do so. I once thought this type of case was much commoner in private than in hospital practice, but I doubt if this is true. There is more time in private practice to discover them. The discovery must be achieved in hospital practice as well, and achieved by us and not passed on to a specialist in psychological medicine.

While I am one of the few remaining users of the guillotine, I have watched the changing attitude towards the removing of tonsils and adenoids, and I am delighted to see that there now is that "conservation of the lymphoid tissue of the upper respiratory tract" which T. B. Layton, my teacher, so eloquently preached all his life.

I took part in the development of endoscopy. In my early registrar days, the triumph we prayed for was the successful removal of a foreign body from the bronchus. More often we had to rescue a foreign body from the œsophagus—an anxious emergency—each time potentially saving a life. We diagnosed œsophageal malignancy and sometimes stretched

old strictures. At this time the range of endoscopy was widening. I had the good fortune to work with a general surgical registrar who was interested in the possibilities of thoracic surgery and, together, we were officially designated an endoscopic team in our hospital. We quickly demonstrated the value of bronchoscopy in the investigation and treatment of disease of the lungs and we made some elementary efforts at treating or alleviating malignant disease of the bronchi by endoscopic attack. But as soon as surgery of the thorax became as safe as surgery of the abdomen, it seemed inevitable that the endoscopy of the thoracic contents should pass to the thoracic surgeon. In my opinion, we should limit our endoscopic work to the neck. The improvements in general anæsthesia and, later on, the protection imparted by antibiotic drugs, have provided increasing factors of safety in endoscopy. But these particular benefits have been most dramatically of value in the major surgery of the larynx and pharynx. By such means the treatment of malignant disease in this region, by surgery, has reached a degree of success dependent only on the skill of the surgeon and the limits of the disease. Improvements in radiotherapy potential, and technique, are also constantly occurring, and the contest between surgery and radiotherapy in the treatment of malignant disease seems to be more clearly defined—unhampered now by the risks of surgery and the discomforts of radiotherapy.

During the last thirty years, improvements in public health, in housing and in diet for large sections of the community, with especial reference to children, have resulted in less upper respiratory disease, the control of diphtheria, changes in the incidence of tuberculosis and the almost complete disappearance of atrophic rhinitis.

More recently the advent of chemotherapy and antibiotics has started a new era in medicine and surgery, but has been especially forceful in our specialty. In addition to the general benefits, with regard to pyogenic infections, with which our regions can abound, there have been very especial local benefits in tuberculosis and syphilis. These diseases are now rarely seen within the larynx.

In the last ten years or so, some very subtle changes in our work have been occurring as a result of the antibiotic era. The ability to treat and cure acute infections is self-evident, but I refer, rather, to the secondary effect of this curing of acute disease—namely the gradual disappearance of chronic infective and inflammatory changes. This is being revealed now, especially in regard to the lymphoid tissue and in regard to the sinuses. I find in all sections of the community an increasing decline in the numbers of patients needing tonsillectomy or operations on sinuses.

So, where are we to-day? What does the present-day laryngologist do?—or what is there left for him to do?:

He diagnoses and treats—partly surgically—malignant disease in larynx, pharynx and nose.

He treats some acute upper respiratory infections and may have to operate on account of the results of acute infections.

He may need to operate to correct abnormalities of development or injuries toward the general design of a restoration of function.

He has to deal with allergy as manifested in the nose and throat.

He has to discover and deal with psychosomatic illness.

He has to listen to a vast multitude of complaints for which he can find no cause!

Some weeks ago I read that the discoveries of the laryngoscope and of cocaine were important landmarks in the history of our work. I wondered about other landmarks and decided that the establishment of endoscopy was another; then the perfecting of intratracheal anæsthesia exerted a great influence on much of our surgical work, extending the margin of safety and widening the scope. Lastly, the discovery of antibiotics had a very special significance for us. I then dated these landmarks and noticed an interesting sequence. I knew that cocaine was discovered in 1880. Twenty years earlier, 1860 was a fair date for the discovery of the laryngoscope. Twenty years later, 1900 was not far wrong for the endoscopic landmark. Add another twenty and intratracheal anæsthesia was then being more widely used, while 1940 seemed an excellent date for the antibiotic miracle. One is tempted then to wonder what is next on the list? What is put down for 1960? If it is to be an improvement in radiation therapy of malignant disease or some other revolutionary treatment of such disease, then the quota of surgery in the life of a laryngologist is almost gone.

I have always been interested in the teaching of medical students and of newcomers to the specialty. There has been some tendency in recent years for young men already trained in general surgery to consider a further training in laryngology and joining our specialty. We would all agree that this is an excellent sequence, but I do feel it necessary, at present, to ask such trainees why they are wanting to do this—whether they hope they are entering a surgical specialty and warning them that this may not be so.

In our specialty do we continue within the limitations of our predecessors, accepting the occasional amputation of sections of our work and watching the transferring of emphasis from surgical to non-surgical treatment of the majority of our patients? That way, we must again become physicians or even disappear!

Is it right, then, that the emphasis on training and qualification should be surgical? The "Surgeon in Charge" and the "obtaining of higher qualifications in surgery"—are these phrases becoming outmoded? May the laryngologist of the future possess a higher medical qualification?—may he, like Semon, take the M.R.C.P. and become a Fellow of the Royal College of Physicians and not a Fellow of the Royal College of Surgeons? I am being controversial and provocative as I feel we must, for the sake of our young men and women and, therefore, for the sake of the future of this Section, think on these things.

There *are* some sections of surgical work which might be in our province. Some once were—for instance, the thyroid gland—a development from the floor of the pharynx and lying in the middle of our present territory. Who better equipped with instruments and with technique than ourselves for dealing with a cleft palate, and why not the cleft lip with its gap into the nasal cavity? With so much familiarity with the anatomy of the neck, why should we not seek out the sympathetic chain as well? and why should we not regard the tongue and the salivary glands as being within our surgical province?

Morell Mackenzie in November 1888, during his Presidential Address to the British Laryngological and Rhinological Association, said:

> "*I would urgently recommend the younger members of the Association, whilst devoting themselves to our speciality, to continue to practise general medicine or surgery for the first ten years of their professional career.*"

And in the concluding paragraph of the History of Otolarnygology by Scott Stevenson and Douglas Guthrie, 1949, we read:

> "*The great interest of the speciality . . . is that it still contains so many fascinating and stimulating problems for its practitioners, who must not be allowed to forget that they are physicians as well as surgeons and philosophers as well as craftsmen.*"

I work at Guy's in a part of London known still as the Borough—once the home of many Dickens' characters and now the haunt of his ghosts. Monthly, during the winter, we hold a departmental meeting in the one remaining Inn, "The George". A little farther down the High Street is the site of the old Marshalsea debtors prison and, occupying part of it, is the present Southwark Coroner's Court. It is curious how vividly odd remarks made to one stand out in memory.

On my first official visit to that Court, as a house surgeon, I stood in the witness box to testify regarding the post-mortem findings. I do not remember anything about the patient, I only remember the gentle kindly old gentleman, the Coroner, as he asked me my qualifications—M.R.C.S., L.R.C.P.—"Ah yes! a member of the Royal College of Surgeons and a licentiate of the Royal College of Physicians. Ladies and Gentlemen, I would like you to note that the gentleman in the box is both a surgeon and a physician".

[*November* 26, 1957]

## DISCUSSION: INTRACRANIAL HÆMORRHAGE—DIAGNOSIS AND TREATMENT

**Dr. P. D. Bedford** (The Cowley Road Hospital, Oxford):

Intracranial hæmorrhage may be arterial, capillary or venous, and its anatomical situation extradural, subdural, subarachnoid, intracerebral or ventricular. The term cerebral hæmorrhage is generally applied to cover all forms of bleeding within the cranium.

Any cause of a general hæmorrhagic tendency may be reflected in bleeding from vessels within the skull, but they are, in addition, peculiarly liable to bleed when no such cause is operative. Although many theories have been advanced to explain this phenomenon, none is satisfactory.

As an expression of the general bleeding tendency, intracranial hæmorrhage may occur incidentally, or as a leading symptom, or as a terminal event in any hæmorrhagic disease—the "primary" and "secondary" thrombocytopenic and non-thrombocytopenic purpuras—whatever the affected element may be, either blood, blood vessels, erythropoietic system, or clotting mechanisms. Thus it is seen in a great variety of general medical disorders as well as in hæmatology. It may also occur in the course of many inflammatory and other diseases of the brain and meninges such as tuberculous, syphilitic and carcinomatous meningitis, Wernicke's encephalopathy and the various encephalitides. Such conditions, however, comprise so small a portion of the whole problem that further consideration of them, although of great theoretical and practical interest, is not warranted here.

Diagnosis is often masked by the gravity of the general illness, and where this is not so, the problems of diagnosis and of treatment are similar to those of spontaneously occurring intracranial hæmorrhage with the exception that specific therapy of the causal condition is in many cases now applicable.

Traumatic cerebral hæmorrhage—whether extradural or elsewhere within the cranium (with the exception of chronic and subacute subdural hæmatoma)—is now virtually the realm of the accident surgeons or of those concerned with the management of the newly born.

Hæmorrhage into intracranial tumours—whether primary or secondary—is an uncommon complication, indeed far less common than is generally realized.

The subjects remaining for discussion therefore are subdural hæmatoma, and spontaneous cerebral hæmorrhage (intracranial and subarachnoid).

### Subdural Hæmatoma

*Diagnosis*

The classical syndrome of subacute or chronic subdural hæmatoma is readily recognizable and sets no further diagnostic problem than the constant and vigilant awareness of its possible occurrence. An injury to the head—which may be severe but is often trivial—is followed after a variable interval by an alteration in the level of consciousness which fluctuates slightly or widely between complete clarity and coma, rapidly or slowly during the twenty-four hours, and is accompanied by focal neurological signs usually comprising pupillary abnormalities and evidence of damage to the pyramidal systems. Indications of cerebral compression later become manifest with ingravescent physical signs and symptoms, and the development of papillœdema. The cerebrospinal fluid (C.S.F.) contains red cells and an increased amount of protein, and the pineal gland—if visible radiologically—is seen to be displaced from the mid-line.

Unfortunately, the very clarity of this classical syndrome has led observers into the catastrophic error of supposing that if the case does not conform to this description in whole or in part, the possibility of a subdural effusion can be dismissed.

But in old age this picture is very much the exception and not the rule; it was manifest in only 1 in 10 of my elderly patients (5 of the 52 cases aged 65 and over, seen by me in the eight years ending June 1957). The condition is known to be frequently atypical in infancy too, but here the ease of exploratory needling before the fontanelles have closed makes the problem of diagnosis somewhat less formidable than in old age. It is supposed that the reasons for these diagnostic difficulties are that the shrinkage in brain volume which

occurs in old age, and the ready elastic expansibility of the cranium in infancy, allows an extravasation of considerable volume to collect in the subdural space before the development of local or general symptoms and signs of cerebral compression. I do not find this explanation entirely satisfying, for firstly, the very old and the very young appear to be quite as intolerant of increased intracranial pressure as those in other age groups, and secondly, I have personally been unable to demonstrate an absolute increase in C.S.F. volume in old age in the absence of large zones of cerebral infarction.

I propose to confine my further observations under this heading to the problem of the diagnosis of *subdural hæmatoma in the elderly*.

Typically the history is that the old person, already somewhat enfeebled, has recently become mentally confused: medical advice or admission to hospital is sought for this latter symptom. A history of a fall within the preceding weeks or months may be elicited—usually by direct questioning—and has been attributed to "old age" or to a "little stroke". The fall may have been accompanied by transient unconsciousness or epileptiform jactitations (and it may be observed here that although a fit is only rarely a symptom of subdural hæmatoma, it is by no means a rare cause of the fall which leads to the blow on the head—trivial or otherwise—which is its almost invariable antecedent). Physical examination only rarely contributes substantially to the diagnosis. The usual clinical picture is that of a mentally confused old person with some impairment of intellectual capacity (which may be slight, moderate or profound), who may be somewhat or deeply drowsy—but is as often not—and who may or may not have bruising about the eyes and forehead: there is often evidence of damage to the pyramidal systems, and occasionally pupillary abnormalities not unjustifiably attributable to ocular disease, which also hinders adequate retinoscopy. Very often, too, concomitant disease of other systems—a fractured neck of femur, bronchopneumonia, heart failure or uræmia—provides further diagnostic distraction.

Manifestly, when the semeiology is classical, the diagnosis is as simple in the elderly as in other age groups; but when the picture I have described is presented, the difficulties are formidable. Indeed, despite the utmost vigilance, only 40% of my elderly cases were diagnosed in life (21 of the 52 aged 65 and over), the others being discovered unexpectedly *post mortem;* for impairment of the intellectual faculties is the rule in old age; falls are a commonplace; an upgoing toe and pupillary abnormalities are common expressions of cerebrospinal and ocular degenerative processes; while mental confusion is an almost invariable accompaniment in old age of diseases anywhere in the body, however remote from the brain. Nor have changing neurological signs or fluctuations in the level of consciousness proved in any way pathognomonic, for hourly records show similar vicissitudes in a wide variety of common geriatric disorders—from uræmia to heart failure—and in other intracranial diseases. Although the C.S.F. protein was elevated (above 90 mg./100 ml.) in 25% of my elderly cases (13 of the 52), and red cells were present in 17% (9 out of 52), any value these observations may have is vitiated by the results of routine lumbar puncture performed on over 4,000 elderly patients, which yielded unaccountably high-protein fluids in no less than 12%. Routine radiography of the skull of all confused patients has proved no more revealing, for displacement of the pineal has been manifest in only 10% of my elderly cases (5 of the 52). It is, however, a valuable sign when it can be demonstrated, but all too frequently the pineal is not visible; and even when it is seen, displacement may not be evident, as was the case in 7 unilateral (13%) and 6 (11%) bilateral subdural extravasations. Even air-encephalography and cerebral angiography have been largely futile, for these examinations cannot be performed as routine on every confused patient—nor indeed on anyone without some very firm indication, which is rarely forthcoming in these cases; while physical frailty, mental confusion and lack of co-operation have led, at best, to only a limited examination being possible and much more usually to the abandonment of the study or to inconclusive results. Electroencephalography (EEG) and investigation with radio-active isotopes have proved valueless; and the only infallible diagnostic measure is exploratory craniotomy. But when it is appreciated that over 80% of more than 5,000 patients aged 65 and over, who were admitted in the past eight years to the Oxford Geriatric Unit, were mentally confused, whatever their salient diagnosis, the size of the problem becomes apparent.

It must reluctantly be admitted, therefore, regarding the diagnosis of subdural hæmatoma in the aged, that unless thousands of old people are to be submitted needlessly to unjustifiable intracranial exploration, every physician concerned in their care will see a number of patients each year in whom the condition unavoidably defies detection; and this unsatisfactory state of affairs is not materially improved by the knowledge that even without surgery these effusions are not invariably lethal.

*Treatment*

Treatment of subdural hæmatoma, when the diagnosis is made, is in the first instance surgical.

## Spontaneous Cerebral Hæmorrhage

This has only recently been the subject of a comprehensive discussion (*Proc. R. Soc. Med.*, 1957, **50**, 281). Physicians and surgeons alike agree that the distinction between primary, subarachnoid and intracerebral hæmorrhage is quite arbitrary—"clinically difficult and often artificial" (Falconer, 1956; Holmes, 1957)—and as I am substantially in agreement with this view, I shall consider these conditions under a common heading.

### *Diagnosis*

Of 5,100 patients admitted to the Geriatric Unit, Cowley Road Hospital, Oxford, in the eight years ending June 1957, there were 63 proven cases of spontaneous cerebral hæmorrhage. My remarks are based largely on these 63 cases but I have also taken into account 55 others seen elsewhere—a total of 118. The condition is commoner in men than in women, by a factor of 1·25 to 1 (35 to 28) for the Cowley Road Hospital series, and 1·8 to 1 in the group seen elsewhere. This greater incidence in males is generally agreed (*see* Wilson, 1955). (Cerebral thrombosis was twenty-one times more common than hæmorrhage in the hospital patients—1,337 to 63 respectively—whereas it was only six times more frequent in those seen elsewhere.) A comparison with Murphy's (1954) figures of 3·25 to 1 and with those of Carter (1957) of 0·7 to 1 forces the conclusion that these are all biased groups and that the true ratio of thrombosis to hæmorrhage is still not known. The diagnosis is often mistaken—as subsequent post-mortem studies have shown—and Wilson's (1955) observation that "the diagnosis (of cerebral hæmorrhage) is still often (erroneously) made for death in old age"—is certainly true.

By far the commonest single associated finding—if not necessarily the cause—of spontaneous cerebral hæmorrhage was hypertension, no less than 80% of all the men and 75% of the women having diastolic pressures of 100 mm.Hg or more. This is in substantial agreement with Russell (1954) who attributed 50% of her 461 necropsy cases of spontaneous intracranial hæmorrhage to hypertensive cerebrovascular disease.

After an exhaustive clinical and post-mortem study of my cases and of the literature, I have little to add to current views and knowledge regarding the diagnosis of spontaneous cerebral hæmorrhage. Some findings which have emerged will be itemized for brevity as random and dogmatic jottings.

(1) Neither old age nor co-existing hypertension should be a bar to the diagnosis of hæmorrhage due to congenital aneurysm. Falconer (1956), Henson (1957), and Rowley *et al.* (1957) have all emphasized that many congenital aneurysms bleed for the first time in old age; while 18 of my cases clearly demonstrate that hypertension and congenital aneurysm are by no means mutually exclusive conditions.

(2) The most important single cause of cerebral hæmorrhage other than that due to trauma, aneurysm, or vascular hamartoma, is degeneration of the media (Turnbull, 1915) of which hypertension is by far the commonest cause, and in which atherosclerosis, although frequently concomitant, plays an uncertain but subsidiary role.

(3) There are no features by which a cerebral hæmorrhage may be predicted in a hypertensive patient—neither "little strokes", nor retinopathy, nor the cause, character or severity of the hypertension: I am here in full agreement with Leishman's (1957) conclusions. There are, furthermore, no apparent features by which the event may be anticipated in the normotensive individual.

(4) Cerebral hæmorrhage is by no means always fatal. I feel that Rose (1948) in his study of post-mortem material paints rather too sombre a picture. I agree with Potter (1956) that "spontaneous recovery to a variable degree may take place, and this may occasionally be assisted beneficially by the surgical evacuation of a clot that is refractory to the natural process of absorption". His statement, however, that "the patient may then survive a year or two . . ." is too pessimistic for I have seen several who have lived for much longer periods.

The commonly-held beliefs that ventricular hæmorrhage is invariably fatal, and that rupture of an intracerebral hæmorrhage into the subarachnoid space relieves the pressure and is therefore of better prognosis, are very frequently erroneous.

(5) As between thrombosis and hæmorrhage, the diagnosis can be impossible in the early, and sometimes in the later stages too. Three reasons for this difficulty are:

*a*) Blood in the C.S.F. is not diagnostic of free hæmorrhage since it has also not rarely been observed in the early stages following thrombotic infarction; while a xanthochromic or high-protein C.S.F. later on is by no means exceptional in the latter.

*b*) Blood may not be found in the C.S.F. in undoubted cases of cerebral hæmorrhage: this has also been emphasized by Rose (1948).

*c*) Even *post mortem* the distinction between cerebral hæmorrhage, and red infarction due to thrombosis, may not be easy, especially as no thrombus is to be found in 60% of

thrombotic cases (Murphy, 1954); and because no cause is to be found in 20% of cases of hæmorrhage (Potter, 1956)—which figure agrees with the 17% in my own series.

(6) The differential diagnosis between subarachnoid bleeding and other intracranial lesions can also be difficult in the early stages. Two reasons for this are:

(*a*) Meningism may be absent in subarachnoid hæmorrhage even in the absence of deep coma, and conversely may be present without blood in the C.S.F. or a C.S.F. pleocytosis. (The former is quite common, of course, in expanding lesions of the posterior cranial fossa and is also not rare in extracranial conditions.)

(*b*) The observation that in subarachnoid hæmorrhage a neutrophil or a lymphocytic pleocytosis without blood in the C.S.F. may occasionally occur (Holmes, 1957) and may lead to the erroneous diagnosis of brain abscess: my own experience confirms this.

(7) The co-existence of other primarily extracranial causes of cerebral symptoms, and signs including papillœdema, can occasionally be a source of great difficulty and may lead on the one hand to the erroneous diagnosis of cerebral hæmorrhage, and on the other to its presence being missed. This difficulty has arisen in my 4 cases of cerebral infarction associated with cor pulmonale (Bedford, 1956), and also in cerebral vascular insufficiency states in patients with malignant hypertension.

(8) In the diagnosis of intracerebral clot, any change whatever in symptomatology or neurological signs following partial or apparently complete recovery from an apoplexy should call attention to its possibility. Serial EEG studies have proved of considerable value in its detection; and air encephalography or cerebral angiography is indicated with a view to surgical evacuation.

(9) Many other investigations, such as the capillary fragility test and examination of the blood for neutrophil leucocytosis or bilirubinæmia, have at one time and another been advocated but are of no specific value in the differential diagnosis of spontaneous cerebral hæmorrhage.

*Treatment*

Consideration of the problems of treatment of intracranial hæmorrhage, whatever its type, situation, or cause, falls under six headings:

(1) Prophylaxis—i.e. the treatment of any predisposing condition.

(2) Prevention of further hæmorrhage.

(3) Evacuation of harmful extravasation of fluid blood or clot.

(4) Management of the unconscious patient in general (the prevention and treatment of bedsores, and of pulmonary, urinary, metabolic, cardiac, oral and bowel complications).

(5) Management of the "cerebral case" in particular—(post-operative and others)—with especial reference to cerebral compression, œdema, and hypoxia; hyperpyrexia; some peculiar metabolic derangements; and agitated mental confusion.

(6) Problems of later management—of such sequelæ as paralysis of function and epilepsy, and of mental confusion, dementia and other psychiatric disorders.

I propose to deal very briefly here with these problems.

(1) The prophylaxis of cerebral hæmorrhage lies essentially in the prevention of by far its commonest cause, namely hypertensive cerebrovascular disease. As the fibrinoid medial degeneration in this condition is probably reversible in its early stages, it is to be hoped that early and effective hypotensive therapy will materially reduce the incidence of cerebral hæmorrhage (Leishman, 1957). The mental confusion of hypertensive cerebrovascular disease—and particularly in the elderly—is almost invariably aggravated by effective hypotensive treatment. It is probable that in these cases the fall in blood pressure produces a state of cerebral vascular insufficiency (Corday *et al.*, 1953) by reducing the blood flow through vessels whose lumen is already irreversibly narrowed (Kety, 1955; Brain, 1956; Millikan *et al.*, 1956).

(2) In the prevention of further hæmorrhage, medicine has little yet to offer. Hæmostatic agents, Filatov's manœuvre, intravenous aminophylline and a host of other treatments have been advocated from time to time but are valueless. Reducing the blood pressure by hypotensive drugs, although theoretically reasonable, has, in my experience, had similarly discouraging results, but possibly the method has not yet been given an adequate trial. Although radiotherapy has been of value in a few of the uncommon cases of hæmorrhage due to angiomatous malformations of the brain, it is to surgery that one must turn for the only small source of proved comfort. Here I would strongly support the bolder approach against the extremely conservative outlook generally prevalent to-day. I agree firmly with Holmes (1957) who states that "surgery should be considered at an early stage in the management of spontaneous intracranial hæmorrhage with the exception of patients who are moribund when admitted to hospital". (I do not agree however with his implication that old age alone should preclude surgical intervention. Indeed, although I am fully alive to the hazards of operation under general anæsthesia in the elderly (Bedford, 1955)

feel strongly that the general approach to surgery in old people is far too timid and is largely irrational to-day having regard to the recent revolutionary advances in anæsthetic skill and techniques. Obviously, although no operation must be undertaken lightly or casually, the one question to be decided—as with the application of all forms of treatment—is the risk of operating as against the chances when operation is withheld; and in this balance the factor of age alone must not be allowed unduly to weight the scales.)

(3) Evacuation of intracranial blood clot is manifestly the province of surgery, and it is only in the less specific spheres of management (listed under headings (4), (5) and (6) above) that medicine has anything reasonable to offer.

(4) A treatise could be written on the problem of bedsores. All I shall mention here is that muscle necrosis almost invariably precedes and is independent of breakdown of the skin: that the "superficial" bedsore, which is simply a cutaneous abrasion, presents no real difficulty: whereas the treatment of a fully developed bedsore is a formidable problem demanding the same level of surgical skill and attention as is given to all grossly infected open lacerated wounds: prevention is the only solution, but frequent turning of maybe several patients makes heavy demands on nursing staff—who would however be better employed on this simple manœuvre than on the time-honoured routine of rubbing, spirit and powder. We have recently been achieving some promising results with an alternating-pressure mattress developed at Cowley Road Hospital, but it is still at an experimental stage.

(5) In the particular management of the "cerebral case" I support with reserve Henson's (1957) rather more enthusiastic and optimistic opinion of the value of hypothermia in cerebral ischæmia, œdema and hypoxia. It certainly, however, merits an extended trial.

My two final observations serve only to raise further problems.

First, (*a*) Peculiar biochemical disturbances are sometimes to be observed following cerebral apoplexy, very similar to those described by Higgins *et al.* (1951, 1954) as following head injury: the mechanism of these disturbances is quite unknown. Only very occasionally has the pattern of pituitary or adreno-cortical derangement, sometimes seen, been rectified by treatment with ACTH or adreno-cortical steroids.

And lastly, (*b*) Mystery, too, shrouds the mechanism and cause of the states of hypermetabolism and of the late renal failure that have sometimes been observed, either consecutively, or quite independently one of the other, to follow an apoplexy. It is possible that the release of large amounts of potassium in this hypermetabolic state may be responsible for some of the cases of renal failure that occur following a stroke.

**D. Reginald Kelly** (London):

I propose to confine my remarks to intracerebral hæmorrhage. It has become clear that there are a number of aspects of this condition which are overlooked both in diagnosis and management of these patients. Kinnier Wilson in his famous textbook of Neurology describes the ictus as follows: "The onset is preceded by warnings in the shape of vertigo, headache, or a sense of oppression for a few minutes. Generally speaking a brief second of bewilderment, a cry as of pain, a vague momentary alarm, or a tragic ejaculation such

as 'Oh! My head' heralds profound and immediate insensibility." As regards the prognosis, he cites Jones (1910) whose figures indicated that out of 109 cases of intracerebral hæmorrhage, death ensued in the first twenty-four hours in 37%, within a week in 72%, within a month in 86% (Wilson, 1940). He states that slight prior seizures are more suggestive of thrombosis than hæmorrhage but a single stroke may occur in either; that more or less definite warning and a certain measurable time for development of symptoms characterise an occlusion, but rarely occur in a hæmorrhage; that loss of senses occurs only when a large area is infarcted but is almost invariable with hæmorrhage; and that the commonest site of hæmorrhage is the internal capsule.

*Treatment*

In most hospitals this is expectant, with physiotherapy for the survivors. The only patients who are referred for surgical treatment are those whose features have led the physician concerned to diagnose either a subarachnoid hæmorrhage or a cerebral tumour, although these are often features which I believe may be characteristic of a cerebral hæmorrhage. Of 34 examples of uncomplicated intracerebral hæmorrhage referred to the neurosurgeons at the Maida Vale Hospital (M.V.H.) the diagnosis of referral was that of subarachnoid hæmorrhage in 15 cases and cerebral tumour in 12.

I have recently been studying the clinical features of all the cases of intracerebral hæmorrhage admitted to St. Thomas' Hospital (S.T.H.) in the past three years—some 34 cases, together with 47 cases of intracerebral hæmorrhage which had been referred for surgical treatment at the M.V.H. Of this latter 47 cases which are of rather highly selected material I have omitted 13 cases which were examples of intracerebral clot complicating a ruptured aneurysm or angioma. I believe that there is no way clinically of deciding whether an intracerebral clot follows the rupture of a diseased or an anomalous vessel, and consequently it seems to me that both types of rupture present the same clinical problem. However, I have omitted these cases because it may well be felt that the behaviour of this particular type of spontaneous bleeding may be entirely different and have a different prognosis.

TABLE I.—CLINICAL FEATURES

| | Gradual | Coma | Headache | Death |
|---|---|---|---|---|
| S. T. H. | 9 | 10 | 14 | 31/34 |
| M. V. H. | 23 | 11 | 15 | 15/31 |

*History* (see Table I)

In the cases which I studied the original ictus was ingravescent in 9 out of the 34 at S.T.H. and in 8 more the patient was, in fact, found either unconscious or incapacitated with no history of how long he had been in that condition or how he had reached it. In only 2 out of the 34 patients did the ictus occur during the night. In the M.V.H. cases 11 of the total had an ictus of sudden onset and the remaining 23 had an ingravescent course lasting from minutes to three days. This greater number in the M.V.H. cases reflects, perhaps, the fact that this was selected material referred to the surgeon as a tumour, particularly because of this ingravescent onset, and in many of them because there had been one or more previous episodes.

*Coma* was apparently by no means a necessary part of the clinical course because only 10 of the S.T.H. cases lost consciousness at the time of the original ictus and only 11 of the M.V.H. cases, in each case less than a third of the total.

*Headache* was recorded from the start in 14 of the S.T.H. cases who were not comatose and in only 15 of the M.V.H. cases. I believe that this low figure may well be due to errors in history taking and partly because many of the conscious patients were aphasic; but even although this is undoubtedly a falsely low figure, it is apparent that headache also is not a necessary factor in the diagnosis.

The history, therefore, is one of a sudden or gradual loss of function over a period of hours to two to three days, sometimes but not always associated with headache. The subsequent course of the illness is one which may well on occasions lead to a suspicion of a tumour. In the majority of cases there is recovery of consciousness with evidence of some brain dysfunction. The condition then remains static for a variable period and finally the patient gradually, occasionally suddenly, deteriorates and dies. The important point as will be readily observed from Table II is that the period of survival after the ictus is

TABLE II.—DURATION OF ILLNESS IN S.T.H. CASES

| | Hours | Days | | | | | | | | | | Weeks | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Sudden | 3–12 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 10 | 12 | 2 | 3 | 4 | 5 | 7 | 11 |
| No. of cases | 2 | 2 | 5 | 5 | 0 | 1 | 0 | 1 | 4 | 1 | 1 | 2 | 3 | 2 | 1 | 2 | 1 | 1 |

hours at least, days and even weeks. 18 of our cases survived one or more weeks, and 7 more than three weeks. In these 34 cases untreated by surgical intervention, 31 eventually died and only 3 survived. Of these 3 survivors none had any recovery of function whatsoever.

The following case histories illustrate the ingravescent nature of the onset of many of these cases and the subsequent course of the illness.

*Case I.*—E. P., aged 50, was attending hospital, with pleurisy. While in Out-patients her husband noticed that her mouth was twisted. On the way home she dropped her handbag in the bus and was unable to hold it properly in her left hand. She walked from the bus stop to her home, but on arriving home was unable to walk upstairs because her left leg was gradually becoming weak. This weakness gradually became more severe so that by the time she was admitted to hospital twenty-four hours later she had a left hemiplegia; she was drowsy but rousable. During the course of the next week she gradually drifted into coma. By the end of the week she was in deep coma, and she died seven days after the onset. This illustrates a gradual onset of disability over seven days.

*Case II.*—A. S., aged 63. On getting up the patient complained that she felt queer but had no other symptoms. At midday when shopping, she complained of feeling ill and was said to have stumbled when she walked but she complained of nothing else at the time. That afternoon the kitchen ceiling fell on her, but not on her head; she then went upstairs saying that she felt rather more ill, putting it down to the emotional trauma of losing her ceiling. She lay down on her bed and two hours afterwards she was found to be unrousable. A total period of onset of eight hours.

*Case III.*—H. N. was admitted for surgical treatment of a stricture. On the day after admission he was found unconscious in the toilet, having complained of headache throughout the morning. On examination then he had a right spastic hemiplegia. By the next day his condition had improved. Thirty-six hours afterwards he was rousable. Forty-eight hours after he was conscious, able to speak and to move the paralysed limbs. He continued to improve for eight days. On the eighth day he was obviously confused and within the next thirty-six hours gradually became more dysphasic, incontinent, slipped into coma and eventually died twenty-four hours later. This is an example of the not uncommon story of the sudden loss of consciousness or of function, followed by gradual recovery, a period when the disturbance is static, and finally a gradual deterioration to death. This story I have found may be spread over thirty-six hours, four or five days, or two to three months. Over the whole of this period of three years only one of the many patients who were brought into the Casualty Department of S.T.H. already dead was shown to have died from a cerebral hæmorrhage.

Fits do not appear to be of any diagnostic significance one way or the other since 2 of the S.T.H. and 2 of the M.V.H. series had fits of one sort or another, either at the commencement of the ictus or as a continuing event after the ictus.

TABLE III.—PHYSICAL SIGNS

| | Papillœdema | Meningeal | Blood | Pupils | Hypertension |
|---|---|---|---|---|---|
| S. T. H. | 9 | 15 | 13/14 | 9 | 19 |
| M. V. H. | 10 | 21 | 23 | 9 | 19 |

*Signs which Aid the Diagnosis* (see Table III)

The physician is confronted with a patient who has a focal disturbance of brain function with or without a disturbance of consciousness. Helpful signs in a differentiation from a thrombosis will be the presence of papillœdema, signs of meningeal irritation and the presence of blood in the cerebrospinal fluid, and finally pupillary changes. A greater proportion of these patients will have persistent hypertension and may well have swollen discs as part of their hypertensive retinopathy, although when examined after the ictus the blood pressure is often normal having been reduced by the effect of the hæmorrhage or thrombosis. However, a considerable number of patients with an intracerebral haemorrhage are normotensive, both before and after the ictus. Consequently the absence of a raised blood pressure is no deterrent to the diagnosis. Of the S.T.H. patients the presence of neck stiffness, of a positive Kernig's sign and irritability was recorded in 15 of the 33 cases alive on admission. In the remaining cases no record, either negative or positive, was made of this sign. Papillœdema was noted in 9 cases and its absence in another 5. I think it is reasonable to suppose that both of these physical signs might have been present in one or two more cases. Blood was found in the cerebrospinal fluid in 13 out of the 14 cases in which this examination was carried out.

In the M.V.H. cases 10 patients had papillœdema, roughly the same percentage as the S.T.H. cases. 21 patients, however, had meningeal signs and 23 of the cases had frank blood in their cerebrospinal fluid: a greater number reflecting the selectivity of the material. Indeed it was this combination which obviously led to the diagnosis of a subarachoid hæmorrhage in mistake. It must be clear, however, from these figures that

a sufficient proportion of these cases in both series had neither papillœdema nor meningeal signs to make it apparent that their absence should not lull the physician into a state of confidence that he is dealing with either a cerebral thrombosis or a tumour rather than a hæmorrhage. In a number of cases, either at the commencement or certainly before death, there was either an ipsilateral or later a bilateral pupillary dilatation and fixation: 9 in each series.

TABLE IV.—SITE OF HÆMORRHAGE AT P.M. OR OPERATION

| | Hemisphere | Front. | Temp. | Pariet. | T.O. | Occip. | F.P. | Caps. | Pontine | Cerebellar |
|---|---|---|---|---|---|---|---|---|---|---|
| S.T.H. cases | 14 | | | | | | | 5 | 1 | 3 |
| M.V.H. cases | | 9 | 8 | 2 | 2 | 1 | 3 | 1 | 2 | 1 |

The site of the hæmorrhage found at post-mortem or operation is set out in Table IV. It will be seen that the majority of hæmorrhages in this series are not capsular; that cerebellar and pontine hæmorrhages are not as excessively rare as had hitherto been thought; that the majority of these hæmorrhages occur in situations where it can be expected that irreparable damage has not necessarily been done and that the hæmorrhage is often easily accessible.

*Treatment*

Ever since subarachnoid hæmorrhages have been treated surgically it has often been found necessary to evacuate a cerebral clot. Similarly Jewesbury pointed out (1947) that cerebral hæmorrhage may present as a slowly progressive destructive lesion, mimicking a tumour. The diagnosis in these cases is made only at operation and the hæmorrhage has been evacuated, often with striking recovery. If, therefore, hæmorrhages can be evacuated, as it were by mistake, or during the process of tackling the technically far more difficult task of dealing radically with an aneurysm or an angioma, why cannot an attitude of surgical aggression be adopted towards simple intracerebral hæmorrhage? The only objection would be that the results do not justify the efforts.

We have seen in the preliminary part of this communication that in the untreated group at S.T.H. 31 out of the 34 patients died. 3 recovered consciousness but continued to live with a severe and irrecoverable disability. At the Prince of Wales Hospital over a period of two years 30 patients were admitted with an undoubted cerebral hæmorrhage; of these 30 patients, 6 of those admitted under my care were subsequently operated on. One of these cases died and the remaining 24 all died. Any method of treatment, therefore, which reduces this mortality considerably has surely established itself, particularly if it may result in recovery of function as well. It is against this background of no recovery and of 55 deaths out of 58 untreated cases, with 3 permanently incapacitated people, that the results of a surgical attack must be weighed.

I have personal experience of only 7 cases treated surgically. Of these 7 cases, 1 died on the day after operation and the remaining 6 recovered and were discharged from hospital. The first of these, A. B., recovered from a state of total aphasia and right hemiplegia to a state where his executive speech was normal but he was unable to read, and he had a slight right hemiparesis. He was, however, back at work until a year later when he had a further vascular accident and died. The second patient, D. W., aged 76, had an occipital hæmorrhage evacuated eight years ago at the age of 68 and recovered completely, apart from a left homonymous hemianopia. The third, T. W., aged 56, had an interesting history. Five weeks before he was admitted, there was an attack of vertigo, and a feeling of faintness. An hour later he started to vomit and did so for two days, when it was noted that he had some difficulty in using the appropriate words and he became confused at odd periods. Four weeks later he was admitted to hospital and while there became more irrational and a left hemiparesis gradually developed with papillœdema. On the tenth day after admission there was an epileptic fit, and on recovering consciousness he was completely dysphasic. He remained semi-comatose with a left hemiplegia until he was operated on a week later. A hæmatoma was entered and fragments of clot were sucked out and five days later at craniotomy a large temporal clot cavity was fully evacuated. The cavity stretched 9 cm. from the tip of the temporal horn backwards.

From that point he slowly improved. In spite of the fact that he had such an extensive hæmorrhage, he returned to work nine months after his operation, his only disability being a slowness of thought and action and a mild spastic dysarthria.

The fourth patient, J. L., was aged 54. He had a sudden onset of a right hemiplegia with dysphasia and a large temporal clot was evacuated four days afterwards. He gradually recovered so that by now, eighteen months afterwards, he is living a reasonable social life and can carry out halting, but otherwise almost normal conversation, and is even taking an interest in his business. The fifth patient, A. M., aged 56, presented with a rapid onset of dementia with papillœdema. He steadily went downhill until he was almost comatose. A large frontal hæmorrhage was evacuated and he recovered consciousness but remains moderately demented and disorientated. From his present progress it would appear as though no further recovery can be expected, but

the picture in this case is complicated by his having peri-arteritis nodosa. The sixth patient, A. S., aged 65, presented with a gradual onset of a left hemiplegia; a deep capsular clot was evacuated and she recovered consciousness but has a dense left hemiplegia.

Out of only 7 cases, therefore, already more are alive than out of the 34 untreated cases and some have recovered sufficiently to return to a normal social life. I have not had the time to follow up the cases of my colleagues at M.V.H. to assess their recovery of function, but the immediate results are encouraging.

Out of 34 cases admitted to the M.V.H. and referred to Mr. Valentine Logue for surgery, 31 were treated surgically. 16 of these 31 cases survived to be discharged from hospital and 9 made considerable recovery of function, and 3 more a complete recovery of function. I have not seen these patients but I have only included in these latter patients those in which the notes of the follow-up clinic make it clear that well over 50% of function has returned. In my opinion the contrast between these two sets of figures establishes conclusively the place of surgery in the treatment of intracerebral hæmorrhage.

A number of objections may be raised to suggest that this treatment is for the most part impracticable. It may be argued that the condition is so catastrophic in its effects and the demise so rapid that there is no time to undertake neurosurgical investigations. The figures in Table II indicate that this is certainly not so. It might be argued that the patients are too old for surgery, but the age of these patients is not great: of the S.T.H. patients, 14 were under 60, and 12 under 70. A further objection may be that with severe hypertensive disease one is merely preserving a vegetable just to await further catastrophes. Not only is this not necessarily so with those who are hypertensive, as the histories of my own patients have indicated, but a number of these patients are not hypertensive at all.

It might be argued that the damage caused by the hæmorrhage is so great that no reasonable recovery could be anticipated and that, therefore, the hæmorrhage should be left alone, but these hæmorrhages often do not destroy so much as separate the fibres of the brain and track between them. These hæmorrhages must be relieved to save life because if they remain of any reasonable size inside the brain they eventually act as a growing space-occupying lesion, increasing in size as the weeks go past, causing more damage by compression until eventually the patient dies. Why these hæmorrhages increase in size we have no certainty, but there is evidence that there is an alteration in the type of protein in the fluid remnants of the clot and it seems to be reasonable to suppose that the fluid acts by osmosis in attracting more fluid into the inside of the cyst cavity.

My conclusions then are that cerebral hæmorrhage does not necessarily present with a dramatic onset, loss of consciousness, or headache; in the majority of cases there are signs of meningeal irritation with frank blood in the cerebrospinal fluid; there is a tendency for some recovery after the onset followed by deterioration and finally death in the vast majority and permanently impaired function in the few survivors. Faced with this bad prognosis, the results of surgical treatment are sufficiently good to justify surgical intervention. If the diagnosis is considered in an otherwise fit patient, then he should be investigated by arteriography, followed by craniotomy and complete evacuation of the fluid cavity and the removal of any vascular anomaly. Age is not any bar, the most important factor in deciding about surgical treatment being the patient's previous condition. If there has been no previous gross intellectual deterioration or other disturbance of function, then whatever his age he is certainly unlikely to be damaged but may well be helped considerably by evacuation.

**Mr. Lawrence S. Walsh** (London):

The patients with spontaneous intracranial hæmorrhage whom I wish to discuss were all admitted to the Neurosurgical Department of St. George's Hospital and most of them were under the care of Mr. Wylie McKissock. The radiological investigations were performed by Dr. James Bull.

Most of the patients with spontaneous intracranial hæmorrhage that we see have a subarachnoid hæmorrhage and in addition many have a subdural, intracerebral or intraventricular hæmorrhage or a combination of these. The findings in our first 461 cases of subarachnoid hæmorrhage were as follows:

Arterial aneurysms 249 = 54%.
Arteriovenous malformations 53 = 11·5%.
Cerebral and cerebellar hæmorrhages 35 = 7·5%.
No lesion shown 124 = 27%.

In our more recent series—which I shall discuss in this paper—cerebral and cerebell hæmorrhages have formed just over 10% of the cases. I do not think that this represen the true proportion as I am sure many are not referred to us.

Between April 1954 and December 1956 there have been 72 cases of primary cerebr hæmorrhage and 5 of cerebellar hæmorrhage.

72 *patients with a cerebral hæmorrhage.*—Most of these patients had a subarachno hæmorrhage in addition. 4 patients had no evidence of hæmorrhage on lumbar punctu and a few did not have a lumbar puncture performed. Most of them had marked impai ment of consciousness, signs of a cerebral hemisphere lesion and some showed signs tentorial herniation with one or both pupils dilated and non-reactive to light. It is usually difficult or impossible to distinguish this condition on clinical grounds from an intra-cerebral hæmorrhage due to an aneurysm or an angioma. It is our custom, therefore, to perform bilateral carotid arteriography as soon as possible after admission to hospital unless the signs of cerebral compression indicate immediate burrholes. The angiogram may show displacement of vessels indicating an intracerebral hæmatoma which is then aspirated through an appropriate burrhole. In a surprisingly high proportion of cases—just under one-third—no significant displacement is shown. In such a patient with the clinical picture previously mentioned we then make post-parietal burrholes and an intra-cerebral hæmatoma is often encountered and aspirated. If not, a ventriculogram is performed, the hæmatoma localized and aspirated through an appropriate burrhole. I would thus like to stress the value of burrholes, with additional ventriculography if indicated, in showing the presence of, and localizing an intracerebral hæmatoma in the presence of a normal arteriogram.

This is exemplified by the following case:

A man of 49 who was hypertensive, had, four days before admission, complained of a sudden severe headache, become comatose and developed a left hemiplegia. Lumbar puncture showed blood-stained C.S.F. The arteriogram was normal.

A ventriculogram was performed and this showed a large hæmatoma cavity in communication with the ventricle in the right frontal region and this was evacuated through a frontal craniotomy but he subsequently died. Post-mortem examination showed the hæmatoma cavity extended downwards into the internal capsule.

This is an unusual situation for a primary intracerebral hæmorrhage. Most of them are in the temporoparietal region, tending to split the white matter just lateral to the ventricle and communicating with the ventricle in the region of the trigone. In some the hæmatoma seems mainly in the thalamus having ruptured upwards into the ventricle and in these latter the chances of successful removal are very slight. This splitting of the white matter mentioned above means that some cerebral tissue may be compressed and not destroyed, so that removal of the hæmatoma may allow of considerable recovery.

Having aspirated the hæmatoma through a burrhole the usual procedure is to perform a craniotomy a few days later when a considerable amount of solid hæmatoma is evacuated and the interior of the cavity inspected. In an appreciable proportion of these patients a vascular abnormality is seen—one which has not been shown by angiography—and dealt with. Occasionally a biopsy taken from the hæmatoma wall has shown histologically the features of an angioma when no abnormality could be seen macroscopically. Still more rarely a small angioma has been found at post-mortem examination when no vascular abnormality was found at operation.

The next two cases illustrate this point.

A male aged 25, who was not hypertensive, had had a subarachnoid hæmorrhage one week before admission to hospital and since then had remained comatose with a left hemiplegia. Bilateral carotid arteriography showed that the anterior cerebral arteries were displaced to the left. The ventriculogram showed a cavity in the right frontal region communicating with the ventricles. A craniotomy was performed and an intracerebral hæmatoma was evacuated. A large thrombosed aneurysm 3 × 2 cm. in size was revealed, arising from the termination of the right internal carotid artery. This was packed and the patient made a good recovery.

A hypertensive female, aged 50, had suddenly become unconscious twenty-four hours before admission to hospital. Lumbar puncture showed blood-stained C.S.F. Bilateral carotid arteriography showed displacement of the anterior cerebral arteries to the right but no vascular abnormality. A left frontal burrhole was made and a hæmatoma aspirated. Later a frontal craniotomy was performed and the hæmatoma evacuated. A small fragment of abnormal tissue was removed and on histological examination this proved to be an angioma.

These 3 cases then exemplify two important points in diagnosis. Firstly that a large hæmatoma may be present with little or no displacement on the arteriogram and second that a vascular abnormality may be present which is not revealed by arteriography.

To return now to the 72 patients with a primary cerebral hæmorrhage. In these

vascular abnormality was shown by arteriogram, operation or post-mortem examination. Most, but not all, of them were hypertensive and the commonest age group was between 51–60 years.

The results in these patients were as follows:

18 were not treated surgically—15 deteriorating and dying before treatment could be carried out. The other 3 were improving and surgical treatment was not thought to be indicated.

54 were operated on, the hæmatoma being evacuated through a burrhole or at craniotomy. Of these 24 died shortly after operation, 2 of other causes.

4 were discharged unchanged and died weeks or months later.

2 were improved and died later of other causes.

4 were improved and died later of a recurrence of intracranial hæmorrhage—in one, at least, it was known to be in the opposite hemisphere.

20 patients survive and of these 10 are well and 10 are more or less disabled.

As one might expect it is the younger patient, with lower blood pressure and less marked neurological signs who does best and it is especially those who have survived some days after the initial attack and whose downward course has been slow who have made the best recovery.

## Cerebellar Hæmorrhage

In this series there were 5 patients who had a primary cerebellar hæmorrhage. 4 of these died and 1 survived.

3 of the 4 patients who died did so before their investigations were complete, one of them from perforation of a chronic duodenal ulcer. The fourth, a man of 70, died three weeks after posterior fossa craniotomy.

The patient who survived was a hypertensive woman of 63 who had a large hæmatoma evacuated from the left cerebellar hemisphere over a year ago and who is now well.

In the past two or three months we have seen at least 6 patients with a primary cerebellar hæmorrhage or with a hæmorrhagic infarct in one cerebellar hemisphere. It may be that this increased incidence is chance or that we are now detecting these cases more frequently.

These patients are usually hypertensive and they show a marked impairment of consciousness. If they are able to speak at all their speech may be unintelligible and this disturbance of speech may be mistaken for dysphasia. There is sometimes a clue to the diagnosis in the history or on examination but often a supratentorial lesion may be suspected.

Bilateral carotid arteriography shows no vascular abnormality but may show widely swept anterior cerebral arteries suggesting hydrocephalus. In the few patients in whom we have performed a vertebral arteriogram it has not been helpful.

Air ventriculography may or may not show dilated lateral ventricles and if the fourth ventricle is filled—by Myodil if necessary—it shows the typical displacement of a cerebellar space-occupying lesion with sometimes an irregular filling defect in the fourth ventricle indicating the presence of hæmatoma.

The treatment is to perform a posterior fossa craniotomy and remove the hæmatoma or hæmorrhagic infarct.

The following 2 cases illustrate some of the features mentioned above:

A hypertensive female aged 48 had, two days before admission, developed a severe headache and became very drowsy. She had a right hemiparesis. Lumbar puncture showed slightly blood-stained xanthochromic C.S.F. Bilateral carotid arteriography showed no abnormality. Ventriculography was performed and this showed a space-occupying lesion in the left cerebellar hemisphere. A posterior fossa craniotomy was performed and the lower, lateral part of the left cerebellar hemisphere was necrotic, congested and infarcted. This was removed and the patient showed a steady improvement after operation.

A 63-year-old, hypertensive female collapsed twenty-four hours before admission to hospital and complained of severe headache. She was drowsy and had a speech disturbance which was thought to be dysphasia. She had a right-sided hemiparesis, which fluctuated considerably, and bilateral extensor plantar responses. Bilateral carotid and vertebral arteriography showed no abnormality. Ventriculography with air showed dilated lateral ventricles but the fourth ventricle could not be seen. A Myodil ventriculogram showed displacement of the fourth ventricle indicating a space-occupying lesion in the right cerebellar hemisphere. At operation a hæmatoma was evacuated from the right cerebellar hemisphere. The patient improved after operation.

In conclusion then I would say that although the percentage of success in treating primary intracerebral hæmatoma is small, surgery has a definite, though probably limited, place in the treatment of these patients.

The patient with a massive hæmorrhage and rapid downward course is unlikely to be helped but those whose condition deteriorates more slowly seem suitable for surgery and sometimes the improvement in their signs is dramatic following evacuation of the hæmatoma.

## BOOK REVIEWS

**Medical Treatment.** By Kenneth MacLean, M.A., M.D., F.R.C.P. (Pp. vii + 696; 50s. 0d.) London: Churchill Ltd. 1957.

This new book on Medical Treatment, written entirely by Dr. Kenneth MacLean except for the chapters on Tropical Diseases, has the very real advantage of uniformity of style and approach to therapeutic problems. It has inevitably, by the same token, the disadvantage that the more specialized sections cannot have that stamp of authority which the expert alone can give. The methods advocated, however, are for the most part clearly given, with balance and the weight of experience, and, together with the descriptions of medical manœuvres with needles, are of sufficient detail to be of real practical value.

The details of treatments are usually preceded by brief descriptions of the problems they are designed to alleviate, or by a discussion of underlying principles, as, for instance, in the chapter on "Fluid and Electrolyte Disturbances", a subject which bristles with difficulty in presentation. There are also useful chapters dealing with treatment by steroid hormones and antibacterial agents, thus avoiding much repetition in the text.

Any reviewer can always find minor points on which he differs from the author. It would seem, for instance, that whilst emphasis is rightly placed on the dangers attendant upon oxygen therapy in patients with cor pulmonale, sufficient weight is not given to its value in that condition. There also seems to be quite a lot of, if not dead, at least dying wood, the morbid state of which is usually duly recognized by the author himself and will doubtless come under the pruning knife in subsequent editions. There is, nevertheless, no lack of the new in therapeutics, and this book is an up-to-date one.

He is a brave man who is willing to edit a book devoted to medical treatment as the task is immense and recurring, and for the courage of a practising physician who writes all himself amazement at his energy can only be surpassed by admiration for his achievement.

**Atlas of Systematic Human Anatomy.** By Gerhard Wolf-Heidegger, M.D., Ph.D. Volume 3. Systema Nervorum—Vasa Sanguinea et Lymphacea. Foreword by G. A. G. Mitchell, O.B.E., T.D., M.B., Ch.M., D.Sc. (Pp. 167; 172 plates; 55s.) Edinburgh and London: E. & S. Livingstone. 1957.

To quote from the foreword by Professor G. A. G. Mitchell "The present volume, like the first, is an outstanding production and is characterized by its wide scope and beautiful drawings". Your reviewer can whole-heartedly endorse this statement.

The atlas contains 172 illustrations of which 160 deal with the central and peripheral nervous system. The illustrations are based on dissections which were specially prepared for this purpose. These were supplemented by other preparations in the Basle Anatomical Institute.

In order to make many of the illustrations in the central nervous system as true and exact as possible and to avoid disturbing their artistic beauty by pointers lines, a corresponding line drawing appears on the adjacent page. As the Parisian Nomina Anatomica of 1955 are now recognized internationally they have been, with few exceptions, used in the atlas.

The author, artists and publishers are to be congratulated for producing such a fine atlas. It can be recommended without reservation.

**Inhalation Analgesia in Childbirth.** By E. H. Seward, M.A., D.M.Oxon., F.F.A. R.C.S., D.Obst.R.C.O.G., and R. Bryce-Smith, M.A., D.M.Oxon., F.F.A. R.C.S. (Pp. viii +58; illustrated; 7s. 6d.) Oxford: Blackwell Scientific Publications. 1957.

For relieving the pains of childbirth, inhalational analgesia is but one of the many available techniques, not one of which can be guaranteed to be completely satisfactory in every case. It is, however, safe, relatively simple, and, if administered with understanding and attention to detail, as effective as any other method; moreover for the unsupervised midwife its scope has recently been enhanced by the introduction of approved inhalers for Trilene as an alternative to the long-established nitrous oxide.

Besides comparing the merits of these two drugs and describing the apparatus available for their administration, this little book admirably expounds the principles of inhalational analgesia and gives clear instructions for obtaining the best results.

Although written primarily as a practical manual for midwives, for whom it can be strongly recommended, it could also be read with advantage by anyone concerned with the management of labour, including many expectant mothers.

The book is well produced with an excellent index, while appendices give the specification for trilene inhalers as laid down by the Medical Research Council, together with extracts of the rules of the Central Midwives Board which are relevant to their use.

There are two minor misprints.

**An Annotated Bibliography of the History of Medicine in Australia.** By Bryan Gandevia, M.D.Melbourne, M.R.A.C.P. Foreword by Sir Gordon Gordon-Taylor, K.B.E., C.B., F.R.C.S. pp. 140; £A1 15s. Sydney: Australasian Medical Publishing Co. Ltd. 1957.

Bibliographies are useful for reference, but often make dull reading. In this scholarly bibliography—obviously a labour of love—compiled by the Hon. Curator of the Medical History Museum, Medical Society of Victoria, Melbourne, the succinct and stimulating annotations considerably enliven the text and often whet one's appetite for reading the original articles. The material is divided into 18 sections which include medical aspects of the discovery and exploration of Australia; medical aspects of England–Australia transport; early colonial medical practice; history of specific diseases in Australia; medical institutions and organizations; biography and autobiography; the Australian contribution to medical and allied sciences; medical journalism; aboriginal medicine. The author's abbreviations of journals are entirely his own, and it is regretted that in the case of articles the inclusive pagination has not been given. The index of personal names and subjects is a model. The price of the book can only be described as a tragedy, for it deserves the widest possible circulation.

**Lumbar Puncture and Spinal Analgesia.** By Sir Robert Macintosh, M.A., D.M., F.R.C.S.Ed., F.F.A. R.C.S. 2nd edit. (Pp. viii + 142; illustrated. 25s.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

Only very minor alterations, chiefly in the references, have been made for the second edition of this now celebrated monograph.

Concise text and excellent illustrations combine to give a lucid description of the relevant anatomy and of the technique of lumbar puncture; while the basic principles of spinal analgesia are clearly expounded with a refreshing absence of the emotional bias which this subject so often engenders.

Due weight is given to the management of the immediate circulatory and respiratory disturbances associated with subarachnoid block, while for the prevention of neurological complications, great stress is rightly laid on the importance of a strict aseptic technique using autoclaved equipment and drugs; though a list of those drugs able to withstand this treatment could be included with advantage.

There is an excellent chapter on headache, but some disappointment may be felt that the later and more serious sequelæ of spinal analgesia are not considered in greater detail, as the fear of these complications still deters many workers from employing this valuable technique.

This well-produced and stimulating little work, which does not claim to be a textbook, can be highly recommended for the houseman about to perform his first lumbar puncture, for all surgeons interested in spinal analgesia, and for every anæsthetist.

**British Pharmaceutical Codex 1954 Supplement 1957.** Published by direction of the Council of the Pharmaceutical Society of Great Britain. (Pp. xiii + 124. £1 7s. 6d.) London: The Pharmaceutical Press. 1957.

Compiled by the Codex Revision Committee of the Pharmaceutical Society, assisted by a number of subcommittees, this Supplement contains 44 new monographs in Part I (among others Chlorpromazine Hydrochloride, Corticotrophin, Hydrocortisone, Prednisolone, &c., and Reserpine) and several amendments which have been published in the *Pharmaceutical Journal* since the British Pharmaceutical Codex was issued. Appendixes (it is refreshing to find this word spelled correctly) describe assay methods for Erythromycin, Hyaluronidase, Phenoxymethyl-penicillin, Polymyxin B sulphate, Injection of Protamine Sulphate and Tetracycline Hydrochloride. This indispensable work of reference concludes with a careful index.

**Simulium and Onchocerciasis in the Northern Territories of the Gold Coast.** By G. Crisp, B.Sc., Ph.D., F.Z.S., F.R.E.S. (Pp. xvi + 171; illustrated. £2 17s. 6d.) London: H. K. Lewis & Co., Ltd., for the British Empire Society for the Blind. 1956.

Dr. Crisp has produced an excellent account of onchocerciasis in the Gold Coast or Ghana, as it has now become. It is based on his work, initiated by the British Empire Society for the Blind, carried out from 1952–55 in the northern territories of the country where half a million of the inhabitants suffer from the disease and about 30,000 are blind. The largest part of the monograph is devoted to the insect vector of the disease, named *Simulium damnosum*. The exact distribution of this fly is described in detail and this information will prove invaluable for future workers in the territory.

Interesting new data on the bionomics of adult *S. damnosum* are reported. The females were found to bite cattle in very large numbers, 110 flies being caught in a hour on one occasion biting the belly of an ox. The extent to which the fly is zoophilic probably varies

[*Continued on p. 22*]

# *Recent Titles in the Modern Trends Series*

## MODERN TRENDS IN GASTRO-ENTEROLOGY—*Second Series*

Edited by F. AVERY JONES, M.D., F.R.C.P. Pp. xviii+417+Index. 153 illustrations. 78s. 6d. net by post 2s. extra.

This second volume in the series is the joint work of physicians and surgeons, anatomists and radiologists who concentrate attention on the many advances achieved in the past five years, relating them to particular diseases, new methods of investigation and the latest therapeutic knowledge.

## MODERN TRENDS IN ENDOCRINOLOGY

Edited by HAROLD GARDINER-HILL, M.D., F.R.C.P. Pp. ix+298+Index. 16 illustrations. 65s. net, by post 1s. 9d. extra.

This new book covers the results of the vast amount of research which has gone into endocrinology over the past ten years, presenting the broadest outlook and emphasizing the modern approach.

## MODERN TRENDS IN GERIATRICS

Edited by WILLIAM HOBSON, B.Sc., M.D., D.P.H. Pp. viii+407+Index. 68 illustrations. 72s. 6d. net, by post 1s. 9d. extra.

The lengthening of the life span has brought about a new awareness regarding the care of the elderly, and this new book makes a timely appearance, for it presents the results of much recent research on both sides of the Atlantic. Nutrition, psychology, skin and respiratory conditions, orthopaedics, hospital care, gynaecological and surgical problems are among the many subjects reviewed.

## MODERN TRENDS IN NEUROLOGY—*Second Series*

Edited by DENIS WILLIAMS, C.B.E., M.D., D.Sc., F.R.C.P. Pp. xi+350+Index. 80 illustrations. 72s. 6d. net, by post 1s. 9d. extra.

The title *Modern Trends* has been followed literally in this Second Series and each section is of marked contemporary interest. A number of chapters are directly concerned with anatomy, physiology and pathology, and since as many are written by surgeons or pathologists as by physicians, this up-to-date book will have a very wide appeal.

## MODERN TRENDS IN BLOOD DISEASES

Edited by JOHN F. WILKINSON, M.D., M.Sc., Ph.D., F.R.C.P., F.R.I.C. Pp. vi+341+Index. 92 illustrations. 2 colour plates. 65s. net, by post 1s. 9d. extra.

". . . to be recommended to general physicians and pathologists wishing to keep abreast with this rapidly advancing branch of medicine. Moreover, the expert hæmatologist will find it a convenient source of information on subjects outside his own special fields."—*The Practitioner.*

## THE TUDOR GOVERNESS

Katherine Champernowne, the daughter of a knight, was appointed governess to the Princess Elizabeth in 1536, when the latter was about three; and as was the custom in those days, she also took control of her household. In 1545, Katherine married a son of John Astley who was first cousin to the ill-fated Anne Boleyn. After the death of Henry VIII, she was imprisoned in the Tower on a charge of high treason, but was released when her Royal Pupil championed her cause. Elizabeth, it is said, was far more bound by affection to her Governess than to any parent.

There are many men and women today whose affection and respect for an old governess is very great, and if they cannot themselves make provision for her she can turn to the **G.B.I.** for help.

## GOVERNESSES' BENEVOLENT INSTITUTION

(*for the benefit of Governesses and private teachers*)
58 VICTORIA STREET, LONDON, S.W.1

from region to region and the degree of variation may constitute an important epidemiological factor. Artificial feeding of adults could only be obtained if large cages were erected over the breeding places and baited animals were introduced during the following days. Flight range and longevity were studied and gave maximum figures of 12 miles and two months respectively. There is an interesting discussion on dry season survival of the insect and it was shown that aestivation probably occurs in *S. damnosum*.

The larval behaviour of *S. damnosum* was studied in even greater detail and many new observations were made. The excellent photographs of breeding places of *Simulium* and the general countryside show very clearly the characteristics of infested regions in Ghana. An interesting feature is the absence of trees in many of the worst districts.

A brief account is given of the incidence of *Onchocerca volvulus* in the fly and in man, while the possibility of an animal reservoir is considered but largely discarded.

The final part of the book is devoted to methods of control of onchocerciasis with particular reference on an attack on the vector. A control plan based on larvicidal treatment of infested rivers is suggested for the elimination of the disease from the most highly infested regions of the country.

**The Epidemiology and Control of Malaria.** By George Macdonald, C.M.G., M.D., F.R.C.P. (Pp. xiv + 201 + xl + 11; illustrated; 30s.) London: Oxford University Press. 1957.

This well-planned book makes a mathematical approach to the problems of malaria to explain the very different pictures presented by this disease in Africa, India, Malaya and other endemic areas.

After touching on the earlier studies of malarial epidemiology through its circumstantial period (up to 1850), the later ætiological development (to 1900) and the more recent biological advances, the author follows numerically the various factors affecting transmission, and suggests that not only is mathematical epidemiology the most important branch of the science, but the only possible means of integrating the remaining data into a completed whole.

In a series of concise chapters, he considers the stages of the parasite in both man and mosquito, analysing in turn all the variables involved. The mean duration of parasitæmia in man, its reciprocal as modified by the proportionate infectivity to mosquitoes, superinfection and its effect on the build up of a heterologous immunity as found with *P. vivax* and *P. falciparum*, the longevity of the vector, its man-biting habits and even the susceptibility of the anopheline to species and strain of parasite are all given mathematical expression.

The reproductive rate is calculated from the chances of survival of the mosquito, its frequency of feeding and the availability of the preferred host. This in turn is modified by the development of immunity in the population and superinfection in man and mosquito, so that one perceives a critical level below which the disease decreases indefinitely.

Sporozoite and parasite rates, dependent on each other, are discussed in connexion with the onset of epidemics, upon which the effect of the differing incubation intervals are stressed. During the epidemic the parasite rate rises to achieve, when immunity sets in, a plateau of equilibrium. But the height of this plateau depends largely on the reproductive rate locally, in that the more often the chance occurs of man being bitten, the more stable the epidemiological condition with less variation from the mean.

The parasite density in age groups and the frequency of parasitæmia is shown to reflect the intensity of infection, and it is pointed out that heavy gametocytæmia is largely restricted to the younger children, reduction occurring after the first year. Restriction to even younger age groups is found if transmission for any reason is suddenly increased; this tends to restore the equilibrium and explains the absence of epidemics in highly endemic regions.

In areas of "unstable" or irregular malaria, no such limitation of susceptibility to the youngest is seen; and many grow up without resistance. Epidemics may then occur suddenly and violently, only to end when immunity develops and gametocytes are restricted.

The author confirms, by a careful examination of data from areas where endemic malaria can be categorized as stable or unstable, that with high transmission the human infection rate shows slight response to changes in the transmission factors, but varies greatly when the normal transmission is low. The species of parasite and the habits of the anopheline in those areas conform to what might be expected.

The distribution of malaria throughout the world is discussed with an outline of the epidemiology in each of the twelve regions. Rightly the attention of the reader is directed elsewhere for more detailed studies.

Malaria control is shown to require a considerable degree of local knowledge of vector habits and rural housing before an effective programme can be drawn up. This is a most useful chapter.

Drugs now in use and their action on parasite and patient are fully described, and their varying effect upon the different strains of parasite and upon patients with different degrees of immunity is stressed.

Imagocidal and Larvicidal programmes are well discussed though the somewhat dogmatic choice of D.D.T. in oil as the best larvicide in all circumstances is open to question. The mechanisms of control, chemical biological and mechanical, are touched on briefly, and it is regrettable that limited space forbade a more detailed account of common breeding places and the larvicide of choice in each case.

Records of anopheline resistance to insecticides are well covered and the division of chlorinated hydrocarbons into two groups with intra but not inter cross resistance developing, is well supported, though Hamon, J. (1953) *Bull. Soc. Path. exot.*, **46**, 454, claimed resistance developed to both groups when only one had been in use.

Finally there are the appendixes, dealing with formulæ devoted to the analysis of the factors affecting malarial transmission, and with those techniques most required by the malariologist. The former, in particular, will delight the heart of the mathematician while the whole subject is dealt with in an interesting, comprehensive and original manner. A most valuable addition to the bibliography of malaria.

**Memoirs of a Golden Age.** By Maurice Davidson. (Pp. xiii + 140; illustrated. 18s. 0d.) Oxford: Basil Blackwell. 1958.

This is a delightful collection of reminiscences, both grave and gay, of student-life at Oxford at the turn of the century, written by one who has a deep affection for his Alma Mater. The memories are not merely medical for we are given many vivid pen-pictures of learned classical scholars, musicians, and theologians, some of whom possessed odd quirks of character and habit, as, for example, the one who would only be measured for his trousers while seated on a chair.

The illustrations are a source of joy and by themselves would make it worth while to possess the book; we specially liked the sketch entitled "Responsions" in which the son addresses his father—"Hallo, father, I'm through, are you?" with the dolorous answer "No".

Every Oxford man and many who, like the reviewer, had not the privilege of being educated at that seat of learning, will enjoy this nostalgic "scrap-book".

The author thinks the spirit of the golden age has departed from Oxford. We are not convinced.

> 'Tis strange, in speaking of a golden age
> We always use the past and future tenses,
> And think how trivial the present stage
> Which crowds its imperfections on our senses;
> Yet may our children term the present date
> The Golden Age of Nineteen fifty-eight.

**Human Blood Coagulation and Its Disorders.** By Rosemary Biggs, B.Sc.(Lond.), Ph.D.(Toronto), M.D.(Lond.), and R. G. Macfarlane, M.A.(Oxon.), M.D.(Lond.), F.R.S. 2nd edit. (Pp. xxv + 476; illustrated; 42s.) Oxford: Blackwell Scientific Publications Ltd. 1957.

The appearance of a new edition within four years of the first is a consequence of the success of this book and also of the rapid advance in knowledge of blood coagulation and the hæmorrhagic disorders.

The authors were unfortunate in that the first edition was published almost simultaneously with two major events in the history of blood-coagulation research: the discovery of Christmas disease and the introduction of the thromboplastin-generation test. The present edition has been better timed; no comparable "break-throughs" in knowledge have taken place during its preparation and the authors have been able to complete their revision comparatively undisturbed by new discoveries. The result is a most readable and authoritative account of blood coagulation and its disorders.

All the new work receives critical mention. Christmas disease, PTA deficiency and von Willebrand's disease are surveyed in detail and an important section is devoted to the hypoprothrombinæmias and Factor-VII deficiency. There is a useful chapter on thrombosis and anticoagulant therapy. The technical section of the book has been expanded and a useful glossary of technical terms appended, in which synonyms for the various clotting factors may be found.

There is much to admire in this book and practically nothing to criticize. The reviewer would, however, like to suggest that some, at least, of the figures be redrawn when the next edition is prepared. Although they show what they are meant to, they are mostly not up to the standard of the rest of the book. Exception could also be taken to the size of the small print in the few places where it is used in the text, e.g. pp. 307–312. It is so small that a magnifying glass is almost a necessity.

## Some Observations on Costen's Mandibular Syndrome: Including a Review of 100 out of 500 Cases

### PRESIDENT'S ADDRESS

By GEORGE T. HANKEY, O.B.E., T.D., F.D.S., M.R.C.S., L.R.C.P.
*London*

#### INTRODUCTION

THE first part of this Address is a short commentary on Costen's syndrome; the second is a review of 100 treated cases of temporomandibular dysfunction out of more than 500. [A colour film of the treatment of a typical case was shown at the Meeting.] The subject matter is complementary to my two previous papers on this subject (Hankey, 1954, 1956) and should, if possible, be read in conjunction with them.

#### PART I.—A BRIEF DISCUSSION OF COSTEN'S SYNDROME

Costen, an American otolaryngologist, ascribed the following syndrome of symptoms to temporomandibular joint dysfunction: (1) Neuralgia of the second or third divisions of the V nerve. (2) Pain in and around the ears. (3) Stuffy sensation in the ears. (4) Pain up the back of the head and down the side of the neck. (5) Headaches, chiefly of the vertex. (6) Sinus pains. (7) Impaired hearing. (8) Tinnitus. (9) Altered sensations of the tongue and throat, including changes of taste.

In a series of papers between 1934 and 1956 Costen analysed a large number of cases and enunciated the hypothesis that the symptoms were due to one or more of the following: (1) Mandibular overclosure with distal condylar displacement and compression of the eustachian tube. (2) Actual direct erosion of the roof of the glenoid fossa and the tympanic plate. (3) Mesial pressure of the condyle on the chorda tympani. (4) Pressure of the retruded condyle on the auriculotemporal nerve.

Anatomically these explanations have not been substantiated (Zimmerman, 1951; Sicher, 1952; Shapiro and Truex, 1943).

Clinically erosion of the roof of the glenoid fossa is extremely rare—it has been found in none of my cases, and ear symptoms other than pain are almost completely absent.

Neuralgia of varying types and degree is the commonest and most distressing symptom, and can only be explained as being reflex in origin from the joint or masticatory muscles. Care must be taken to exclude other causes of pain, e.g. dental, sinus infection, &c. (Harris, 1937).

Although Costen has himself considerably modified his original views, and many of his concepts have since been found untenable, he has rendered a great service in pointing out the relationship between malocclusion, temporomandibular joint dysfunction and facial pain.

#### PART II.—AN ANALYSIS OF 100 TREATED CASES OF TEMPOROMANDIBULAR DYSFUNCTION

These cases comprise a chance collection of 100 out of more than 500 treated by myself privately or in my clinics at The London and St. Bartholomew's Hospitals in the course of the last ten years: 68 of them have been treated since my first analysis of 150 cases in 1953 (Hankey, 1954). This second analysis is put forward partly for comparison with the first but also as an attempt to answer some of the many questions put to me on this subject.

The statistics have been compiled from special Temporomandibular Clinic case-history sheets instituted by myself since 1953 and by means of questionnaire forms filled in at an actual re-examination of the patients in July 1957.

*Sex incidence.*—Table I reveals the same sex incidence as in most other publications on this subject, i.e. 4 females to 1 male. There is no specific reason why females should predominate to this extent.

*Age incidence.*—Table II shows that the 31–40 age-group is the largest and that 74% were aged between 20 and 50—the period when the permanent natural dentition is normally present.

*Symptoms both local and regional. 82 cases.*—Table III shows that 82 of the cases had local symptoms which could be related by the patient to the joint or to mandibular function. The symptoms were the same as previously described by myself (Hankey, 1954, 1955, 1956) and by many others, i.e. clicking with or without pain, occasional locking at first reducible but often eventually irreducible and merging into restricted opening, at first with pain and

spasm of muscles but later becoming painless after fibrous contractions or adhesions had taken place. Others complained of recurrent subluxation either primary or in the joint opposite to the restricted one. The type of pain complained of was spasmodic, short and sharp or else a dull continuous ache and the distribution was usually in the joint itself, up the auriculotemporal nerve, down the inferior dental nerve or along the side of the maxilla. Eating or movements of the mandible aggravated the pain. The fact that the joint or masticatory muscles were in some way involved was clearly indicated. The regional symptoms to be described were often superimposed. Patients in this group were often referred from an orthopædic surgeon.

*Symptoms—regional only.* 18 *cases.*—Table IV tabulates the symptoms of the 18

TABLE IV.—COMPLAINTS OF THE 18 CASES WITH REGIONAL BUT NO JOINT SYMPTOMS

| 10 | Sinus pains .. .. .. .. .. .. | — |
| 11 | Altered taste or sensation of tongue .. .. | — |

NOTE: Many of the patients had a mixture of *symptoms* 1, 2, 3 and 4. *Symptoms* 8, 9, 10 and 11 are conspicuous by their absence.

patients who were unable to relate their complaints to the joint or to mandibular function. They consisted mainly of neuralgias of varying intensity and duration and not always limited to the distribution of the V nerve. The differential diagnosis was more difficult, but after eliminating all other possibilities, the source of the trouble was thought to be in the joint or its musculature. The symptoms described by Costen are included and it is at once apparent that deafness, giddiness, sinus pains and altered lingual sensation are all conspicuous by their absence, which conforms with my previous analysis; the only case with tinnitus also had earache—the pain was cured but not the tinnitus.

Most of this group of patients complained of *symptoms* 1 and 2: that is some form of neuralgia along the distribution of the second and third divisions of the V nerve or of pain in and around the ears. In the first place they often went to the neurologist or the otologist who were unable to account for the symptoms in their field. On examination, however, the pain described by the patient as being in the ear was, in fact, often found to be just anterior to the ear in the joint and on palpation the joint might be tender. This confusion is natural when it is remembered that the auriculotemporal nerve conveys sensation and pain from the anterior surface of the external auditory canal and from the anterior and upper part of the external surface of the tympanic membrane as well as from the joint and temporal region, the postero-inferior part of the external surface of the membrane being supplied by the vagus.

Headaches up the side and on the top of the head, *symptom* 3, were the next most frequent complaint: the area roughly corresponds to that supplied by the middle meningeal artery. A recurrent sensory nerve from the third division of the V nerve re-enters the skull through the foramen spinosum with this artery and supplies the dura mater in the same area of distribution. The pain can therefore be referred from other parts of the third division. So far the pain symptoms are in the area of the trigeminal and could all be due to stimulation of the auriculotemporal branch.

Pain up the back of the head and down the side of the neck and throat, *symptom* 4, is in the area supplied by the second and third cervical spinal nerves and is more difficult to explain in relation to the joint. The area of these nerves borders on and in some part overlaps the area of the trigeminal. Stimulation of II and III cervical can not only cause

pain in their sensory distribution but also, through their motor branches, can cause spasm and stiffness of the neck muscles and sternomastoid. The sensory root fibres of the trigeminal nerve concerned with pain, deep pressure and temperature pass down through the pons and medulla as low as the second cervical segment (Harris, 1937). By synaptic overflow therefore the cervical nerves can be stimulated and give rise to referred pain, the point of origin being in the area of the trigeminal. It has also been noted that infected antra may be the remote cause of spasm and pain of the muscles up the back of the neck.

Muscles in spasm or partial spasm, *symptom* 5, become painful of themselves although inflammation or trauma may have been the original cause of the spasm. If the meniscus or part of the synovial membrane of the temporomandibular joint is accidentally nipped, there is immediate pain; inflammatory reaction and effusion will be followed by some degree of protective muscular spasm to restrict movement and avoid further pain during the period of healing. If the trauma to the joint is chronic the muscular reaction will be the same. Similarly, if the occlusion is at fault and undue or unequal stresses are thrown on certain teeth and their supporting structures then, as pointed out by Ballard (1956) and others, either the teeth are gradually forced into a more comfortable position or they become painful and loose and have to be extracted or, by the agency of the acutely developed proprioceptive senses conveyed in the nerves of the periodontal and supporting tissues, the mandible as a whole by reflex muscular action moves distally, mesially or eccentrically into a bite of accommodation thereby avoiding the painful stimulus. This unnatural movement upsets the normal delicate balance between the muscles on either side of the mandible and may result in muscle spasm and pain without evidence that the joints are also involved. There is a great field here for further electromyographic study. Schwartz and Cobin (1957) are of the opinion that painful spasm of the masticatory muscles is the commonest symptom associated with temporomandibular dysfunction, malocclusion being only a contributory factor.

Pain in the throat or on swallowing, *symptom* 6, may well have a similar muscular explanation for its cause. If the muscles of the neck or mandible or both can be put into a state of tension or spasm through inco-ordinated or unusual movements, then the normally smooth process of swallowing can likewise be disturbed.

Transitory tinnitus and deafness, *symptoms* 7, 8, 9, can be brought on by trauma or infection of the internal pterygoid muscle by spread from an infected wisdom tooth or following an inferior dental nerve block anæsthesia, the reason being that the motor nerve to the tensor tympani and tensor palati muscles comes off the nerve to the internal pterygoid which may be involved. The sensory nerve of the inner surface of the tympanic membrane and the lining of the eustachian tube is a branch of the glossopharyngeal; catarrhal or other blockage of the eustachian tube can cause deafness or deep ear pain but it is impossible for the retruded condyle to effect this by direct pressure.

Sinus pains, *symptom* 10, can be referred to the area of the joint and the reverse is possible, both being within the distribution of the same nerve.

And lastly, altered sensation or pain in the anterior part of the tongue, *symptom* 11, could be referred for the same reason from the joint along the lingual nerve. But the chorda tympani nerve, a branch of VII, has no pain fibres, is concerned with taste only and has no relation close enough to the joint to become involved. Although none of these 100 patients happens to have complained of lingual symptoms, there have been several among the other 400.

One in particular, an edentulous woman aged 70, had been unable to wear her lower full denture for a long time owing to extreme sensitivity and pain of the right anterior two-thirds of the tongue; she had recently only been able to eat the softest of food with great difficulty and was losing weight. The tongue was so tender that she could not tolerate the taking of a lower impression until a right inferior dental and lingual nerve block had been given. She had marked overclosure with condylar retrusion. The lower denture was raised to the correct height with an overlay and before insertion in the mouth a right lingual nerve block with proctocaine was given which lasted for ten days. She was then able to wear the denture which gave support to her mandible and prevented overclosure. At the end of ten days one more lingual Proctocaine injection was given. From then onwards the pain in the tongue disappeared and she was able to eat in comfort.

*Details of the 18 cases with regional symptoms only.*—A higher proportion than usual were male, 11 were over 40 years of age and only 1 under 30. 7 cases were edentulous and all these were overclosed with an increased free-way space, consequent on alveolar absorption with loss of vertical dimension over a period of years or due to full dentures set up at the wrong height *ab initio*. It is interesting to note that only 4 of these 7 edentulous cases showed condylar retrusion on X-ray with the teeth in occlusion: the other 3 had normally placed condyles so that their pain was probably of muscular origin. Among the remainder, loss of molar support was the common occlusal deformity.

X-rays of the joints showed that 9 of the 18 cases, including the 4 edentulous ones, had retruded condyles with the teeth in occlusion; the remainder were normally placed. In

cases where the condyles have been retruded it is usual to believe that the backward pressure on the posterior part of the joint and on the posterior bilaminar attachments of the meniscus where the nerve filaments and vessels supplying the joint are mostly situated, is the origin of the pain; but where the condyles are not so displaced, the pain may well originate in the muscles which are constantly contracting to prevent a displacement which would otherwise occur as a result of malocclusion. Prosthetic bite rehabilitation was provided for all 18 cases by overlaid appliances or by partial or full dentures. All of these 18 cases were eventually much better as the result of treatment and eleven of them were completely cured. None of them was psychopathic.

*Angle's classification and edentulous cases.*—Table V is self-explanatory. More than half the cases had occlusions which could be classified as Angle's Class I; in 6 of these, initially edge to edge, the mandibular incisors had subsided into a labial relation to the uppers owing to lack of molar support and consequent overclosure. Only 27 were Class II: not as many as has previously been supposed.

TABLE V.—ANGLE'S CLASSIFICATION AND EDENTULOUS CASES

| Cross bite .. .. .. .. | | 6 |
| Normal .. .. .. .. .. | | 3 |
| | | 100 |

NOTE: The total number of cases with loss of molar support = 30. 50% of the cases of overclosure were edentulous in one or both jaws. A large number of the cases were also locked against lateral grinding.

*Malocclusions.*—Table VI shows a simplified grouping of the types of malocclusion encountered. 28 were overclosed, of whom half were edentulous; all the edentulous cases were overclosed; 22 had loss of molar support, increased to 30 if 8 overclosed cases are added. Mutilations (haphazard extractions which allow drifting, tilting and over-eruption of the teeth remaining) accounted for 24 cases. Irregularities and cuspal interference 17, cross bites 6, made up the rest. Only 3 could be considered completely normal. It would be interesting to survey a large number of patients to see how many are normal in a civilized community.

*Joint X-ray findings.*—Table VII is shown in order to answer queries as to whether T.M.

TABLE VII.—JOINT X-RAY FINDINGS

joint X-rays are of value, and if they are, what conclusions can be drawn from them. J. R. Thompson in many writings (1946, 1949, 1951) has emphasized the importance of the rest position of the condyles in the glenoid fossæ, particularly in relation to the correction of occlusal deformities, and largely due to his influence it came to be accepted that a pure hinge movement took place in the lower compartment of the joint during closure of the mandible from rest to occlusion and without further translation backwards or upwards of the condyles. Recently, however, Nevakari (1956) has denied this supposition and states that in this same final path of closure the condyle in all cases undergoes a slight translatory movement upwards and backwards averaging 1 mm.—which is very little and difficult, if not impossible, to demonstrate on an ordinary X-ray. A translation during closure from

rest, of more than 2 mm., could therefore still be accepted as abnormal. Husted (1956) is very sceptical about the usefulness of X-ray films to determine the influence of bite displacements on the position of the condyle in the glenoid fossa. There is no doubt that, unless a special detailed technique is employed either by the dental specialist himself, or by the radiographer in the closest association and full understanding of the requirements, many routine X-rays of the joint are valueless, if not misleading. The only variants permissible are the controlled jaw movements; the relative position of the head, film and tube must be static and possible to repeat in an identical manner at the same or a later sitting. (A satisfactory technique for taking transcranial lateral oblique films of the T.M. joint was shown later.) No two patients have condyles or fossæ the same shape or size; often the two sides vary in the same individual, Very rarely will a gross pathology be revealed in these cases of dysfunction or pain; the search is for abnormal movement or displacement.

In this series 34 cases had normal X-ray films. 31 cases showed condylar retrusion with the teeth in occlusion as compared with the resting position; 16 of these were retruded on one side only suggesting a lateral displacement of the mandible by cuspal interference as opposed to centric closure. 15 were retruded on both sides suggesting a displacement backwards of the mandible as a whole. 7 cases showed condylar subluxation when the mouth was wide open, often in Angle's Class III or pseudo Class III occlusions, sometimes on one side only when the other was restricted. 20 cases showed limited forward movement of the condyles on opening, suggesting meniscal block or muscle spasm or both. Only 8 cases showed pathological change of joint outline—1 due to osteoarthritis, 2 to generalized rheumatoid arthritis, 1 to Neisserian infection, 1 to osteochondritis of the condyle, and 3 to congenitally malformed condyles.

*Psychiatric assessment.*—Table VIII is an effort to answer the suggestion frequently

TABLE VIII.—PSYCHIATRIC ASSESSMENT

| | Sex | Age group | Result | |
|---|---|---|---|---|
| Psycho-neurotic | F | 20 | Cure | |
| | F | 20 | Cure | |
| | M | 40 | Unchanged | |
| | | | | 3 |
| Anxiety neurosis | F | 50 | Better | |
| | F | 40 | Cure | |
| | F | 30 | Cure | |
| | F | 30 | Cure | |
| | F | 20 | Better | |
| | F | 10 | Better | |
| | M | 30 | Cure | |
| | M | 30 | Better | |
| | M | 30 | Unchanged | |
| | | | | 9 |
| | | | | 12 |

*Summary*:

Average age over 30 excepting 4 females:

| | |
|---|---|
| 5 females, 1 male—cured .. .. | 6 |
| 3 females, 1 male—better .. .. | 4 |
| 2 males—unchanged .. | 2 |
| 8 4 | 12 |

Psychological reaction of remainder was average for patients attending a hospital for medical treatment.

made that a large proportion of the patients complaining of mandibular syndrome symptoms are neurotic. Out of these 100 patients only 3 were definitely diagnosed as psychoneurotic; 9 more suffered from a lesser degree of anxiety neurosis, and there were a few more women who manifested menopausal instability. It is interesting to note that 4 of these 12 cases were male and that the only 2 cases not improved by treatment were also male. Of the 12, 6 were cured of their mandibular syndrome, 4 were much improved, 2 were no better. The average age of these patients was 30 years or more except for 4 young females. By and large it seemed that the psychological reaction of the rest of these 100 patients was average and what is to be expected of a patient attending a large hospital for medical treatment.

Staton (1955) reviewed a group of patients suffering from mandibular syndrome symptoms from the psychosomatic aspect. He considers that a mild neurosis occurs in all types of patients attending for medical treatment, but that the syndrome may occur coincidentally without relation to neurosis. He accepts the possibility of a psychosomatic precipitation factor in the initiation of pain episodes and that the onset of symptoms may coincide with emotional stress, anxiety or tension state and may terminate with it, but that this should not deviate attention from applying accepted and established therapy. With the physical correction of anatomical derangement, the psychosomatic precipitation of painful episodes should become impossible.

*Treatment.*—Table IX shows the relative frequency of employment of the various lines of treatment of these cases. Almost 80% were supplied with some form of removable prosthetic appliance because it was impossible to take the strain off the joints, relieve muscle spasm and provide a reasonable, balanced occlusion in a centric relation by other means. It is, of course, possible to rehabilitate some occlusions by means of fixed onlays

TABLE IX.—TREATMENT

| | | | |
|---|---|---|---|
| Voluntary muscle control and exercises | 17 | Training flange | 2 |
| Physiotherapy | 31 | Orthodontia | 6 |
| Immobilization | 7 | Extractions—8 for wisdoms | 20 |
| Selective cuspal grinding | 17 | Meniscectomy | 5 |
| Joint injections—8 hydrocortisone 2 sclerosant | 10 | Prosthetic appliances | 79 |

NOTE.—Two or more lines of treatment were often used on the same patient, but the figures show the percentage frequency of employment of each kind.

and bridges, but this type of work is terribly time-consuming, extremely expensive and involves the highest technical skill only possessed by specialists in crown and bridge work. It is therefore only available for the few, and impracticable in a State medical service, not to mention the fact that nothing is worse for a painful joint accompanied by muscle spasm than long hours in the chair with the mouth open especially when it is remembered that very often the commencement of joint symptoms dates from just such a session. Moreover in several instances the mandibular syndrome has been the direct result of crown and bridge work which, far from rehabilitating the bite, has produced unnatural strains and stresses and thrown the occlusion off centric. A removable plastic overlaid appliance is easily and cheaply made with the minimum of inconvenience to the patient and supplies an immediate remedy for the pain; later, when the spasm and pain have been relieved, it can sometimes be worn less and less, perhaps only at night, or eventually discarded altogether. Others who have many teeth missing, have to wear a permanent appliance which serves both as an overlay and as a denture.

Among the 21 patients who were not treated with prosthetic appliances were those with only minor degrees of malocclusion which could be cured by selective grinding, muscle exercises and self-control. It is also clear from the figures that many patients required several lines of treatment.

Injections into the periarticular tissues and joint cavities of hydrocortisone have proved of great benefit in cases whose pain was not relieved by bite rehabilitation alone or in whom there was an established mild degree of osteoarthritis. Strean (1957) has recently published an excellent monograph on the uses of cortisone in dentistry. Pinkey (1955) reports the effect of hydrocortisone on some 350 patients suffering from mandibular syndrome. Its use is empirical, non-specific and purely palliative; its real action is unknown, but it relieves pain and probably aids in the healing of injured tissues. It should be used only as an adjunct to basic dental treatment. The actual intra-articular injection of 1 c.c. of hydrocortisone using a 2 c.c. glass record syringe with a 22 gauge needle, is quite simple and painless if preceded by a superficial and periarticular injection of about 1 c.c. of 2% Xylocaine, using a fine needle. The joint is most easily entered from behind when the mouth is half-open and the condyle is drawn forwards. The point of entry, by palpation, is about $\frac{1}{2}$ in. anterior to the tragus of the ear. Loose, recurrently subluxating joints can be injected in the same way with a mild sclerosant such as sodium psylliate or a 2% phenol in glycerin and glucose, in order to cause a contraction of the capsule. Endografen is an excellent contrast agent for arthrography, gives no painful reaction and is rapidly absorbed. The only disturbing feature for the patient of these injections is an occasional but purely temporary facial palsy brought on by the Xylocaine; the patient should be warned of the possibility beforehand.

Unilateral meniscectomy was performed on 5 cases out of the 100, and all of these were among my early cases treated prior to 1953. Operation was only recommended after all conservative treatment had failed and where there was an obvious meniscal displacement or obstruction with continued pain. In all cases the operation cured the pain but forward condylar translation afterwards tended to be restricted owing to capsular contraction. Sometimes the originally unaffected joint then became overmobile by way of compensation for the limited movement of the operated side and later tended to give trouble. It would seem that balanced and equal muscular action on both sides is of great importance and it is debatable whether the meniscectomy should not be bilateral. The patient only needs to be in hospital about a week for meniscectomy and there is no visible post-operative scar. Exercises or even a training flange should be instituted as soon afterwards as possible in order to obtain the maximum condylar movement. Rehabilitation of the bite is still essential after the operation. In my first 150 cases, 16% underwent surgery (Hankey, 1954), in the next 260 only 3% (Hankey, 1956), and since then an even smaller percentage.

The rationale of bite rehabilitation in the treatment of temporomandibular dysfunction has been dealt with in detail in my previous papers to which reference has already been made. In brief, however, the aim in all cases of mandibular syndrome attributable to malocclusion is to restore that occlusion to the normal centric level and to maintain it in equilibrium so that the teeth can grind freely in all directions without locking, bumping or unequal muscular strains and so that the condyles at the same time are symmetrically

placed and correspond as closely as possible to their resting positions when the teeth or appliances come together in function.

TABLE X.—PROSTHETIC DETAILS

| | |
|---|---|
| Trial acrylic overlays: upper 4, lower 28 | 32 |
| Permanent chrome-cobalt overlays (after trial acrylic): upper 4, lower 14 | 18 |
| Permanent full dentures | 14 |
| Permanent partial dentures | 9 |
| Orthodontic appliances | 6 |
| No prosthetic treatment | 15 |
| Did not return after 1 visit | 6 |
| | 100 |

NOTE: The final permanent overlay figure will probably lie between 20% and 25%. The overlays and full dentures increased the vertical dimension, and provided a balanced occlusion which could grind freely in all directions, and permit the mandible to find its natural centric relation.

*Prosthetic details.*—Table X shows the types of appliances made for those 79 in Table IX who needed prosthetic aids and at the same time it demonstrates the percentage of cases who needed permanent appliances. 50 cases were fitted with acrylic overlays and of these 18 were later fitted with permanent chrome-cobalt skeleton type overlays; a time-consuming, highly skilled mechanical project. It is likely that the final permanent overlay figure will be as high as 25; the output of the laboratory is a limiting factor. Patients for permanent appliances are taken in rotation; in the meantime new cases in pain have to be dealt with by priority and supplied with trial acrylic appliances. This means that the trial appliances have to be worn a long time. On average they are very comfortable if streamlined and made as small as possible consistent with strength, and with the maximum tongue room.

The 14 overclosed edentulous cases all required permanent full dentures raised to the correct vertical dimension. In the first instance it is often a good plan to fix a trial acrylic overlay to the old lower in order to find the correct and most comfortable occlusion; the new denture is later made to this height and bite.

The overlays and full dentures, all increasing the vertical dimension, together totalled 64% and of these, 32 were permanent and 9 more cases required partial tooth-borne dentures without opening the bite. 6 under 20 years of age were treated orthodontically. 15 cases did not require prosthetic appliances, but every case necessitated the taking of impressions, face-bow readings and the mounting of the models on the dentatus articulator. 6 cases did not return for further treatment after the first visit, but all returned for examination or answered the questionnaire in July 1957.

*Attendances for treatment.*—Table XI gives an idea of the average number of attendances

TABLE XI.—AVERAGE NUMBER OF ATTENDANCES FOR TREATMENT

| | |
|---|---|
| Initial examination, investigation and first appliance | 5 visits spread over two months |
| Follow-up, for adjustment, &c. | 3 visits spread over next four months |
| Permanent appliance (after six months' interval or more) | 4 visits spread over one month |
| Averaging | 12 visits spread over twelve months |

Physiotherapy, short wave diathermy, involved additional attendances, e.g. 3 visits per week for four weeks.

of each patient necessary for prosthetic treatment and the amount of time involved. In addition there must be reckoned the mechanic's time spent in the laboratory in the making of the appliances and any additional attendances necessary for physiotherapy, &c.

On average 5 visits spread over two months from initial examination to fitting of trial appliance were necessary per patient; 3 more visits spread over the next four months for adjustment and follow-up were often needed. If a permanent appliance was essential later, 4 more visits were entailed. Such a patient would have to attend at least 12 times in the course of a year.

It can therefore be readily understood that the work of a temporomandibular clinic rapidly accumulates and that it requires the services of a highly trained staff to deal with it efficiently.

*Caries incidence under 50 overlays in Table X.*—Table XII shows that 5 of the 50 cases wearing movable overlaid appliances developed superficial enamel caries of the teeth beneath them apparently in spite of reasonable oral hygiene, but probably the hygiene was not as good as stated; with improved instruction and care it should be possible to lower this figure. The remainder did not seem to be more prone to caries than the average.

*Results of treatment.*—Table XIII shows that, following treatment, 60 of the 100 cases were completely cured and another 34 were much improved but not entirely free from symptoms. The time factor for improvement or cure is also shown; 51% were cured within

TABLE XII.—CARIES UNDER 50 OVERLAYS

| | |
|---|---|
| In spite of reasonable care—5 cases = 10% | |
| Remainder | —normal incidence |

TABLE XIII.—RESULTS OF TREATMENT

| | | | | |
|---|---|---|---|---|
| Improved | 4 months | .. .. | 23 | |
| | 12 ,, | .. .. | 8 | 34 |
| | 24 ,, | .. .. | 3 | |

| Unchanged | .. .. | .. .. | 6 | |
| | | | 100 | |

seven months; another 31% were much better within twelve months, the remainder took anything up to two years. Only 6 cases remained much the same and failed to respond to treatment. An assessment and analysis of the failures must be made in the future. The percentage of absolute cures is not as high as in my previous analysis, but perhaps this can be partly explained by the fact that as time goes on a higher percentage of difficult cases are referred to my clinics for treatment while the less difficult ones are dealt with locally.

A colour film, with sound commentary, was then shown. The film demonstrated the examination, investigation and treatment of a typical case of temporomandibular dysfunction.

SUMMARY

The ear symptoms described by Costen in his mandibular syndrome, except for pain, are almost non-existent: but the neuralgias are very real.

Distressing facial, head and neck neuralgias without joint symptoms but due to mandibular displacement or muscular tension, were present in 18 out of 100 cases; these 100 cases are reviewed.

An explanation for the wide area covered by the neuralgias is given.

34% of the T.M. joint X-rays appeared normal, 58% showed abnormal condylar movement, 8% showed pathological change.

3% of the patients were definitely psychoneurotic: another 9% suffered from a mild anxiety state.

97% had some form of malocclusion.

79% required prosthetic appliances. 8% were helped by intracapsular injections of hydrocortisone: 5% required meniscectomy.

20% required permanent overlaid appliances: another 30% required trial overlays.

A 10% increase of caries incidence beneath the 50 overlays was found (5% of the total).

60% were cured, 34% much improved, 6% unchanged.

Average number of attendances for conservative treatment was 8, spread over six months.

*Acknowledgments.*—My grateful thanks are due to my many professional colleagues for their co-operation in the collection of the material for this paper, but especially to Mr. J. L. Marsden, senior registrar, and Mr. W. E. Berwick, registrar, for their help in the re-examination of the cases and in the staging of the film.

For the making of the film I am indebted to Mr. M. K. Harrison, medical photographer, who did all the photography, to Mr. Love, senior radiographer, for the section on radiography of the T.M. joint, to Mr. J. Elliot, senior surgical technician, for demonstrating the laboratory techniques, and to the various other members of the staff of the Dental Department, St. Bartholomew's Hospital, for their enthusiastic support.

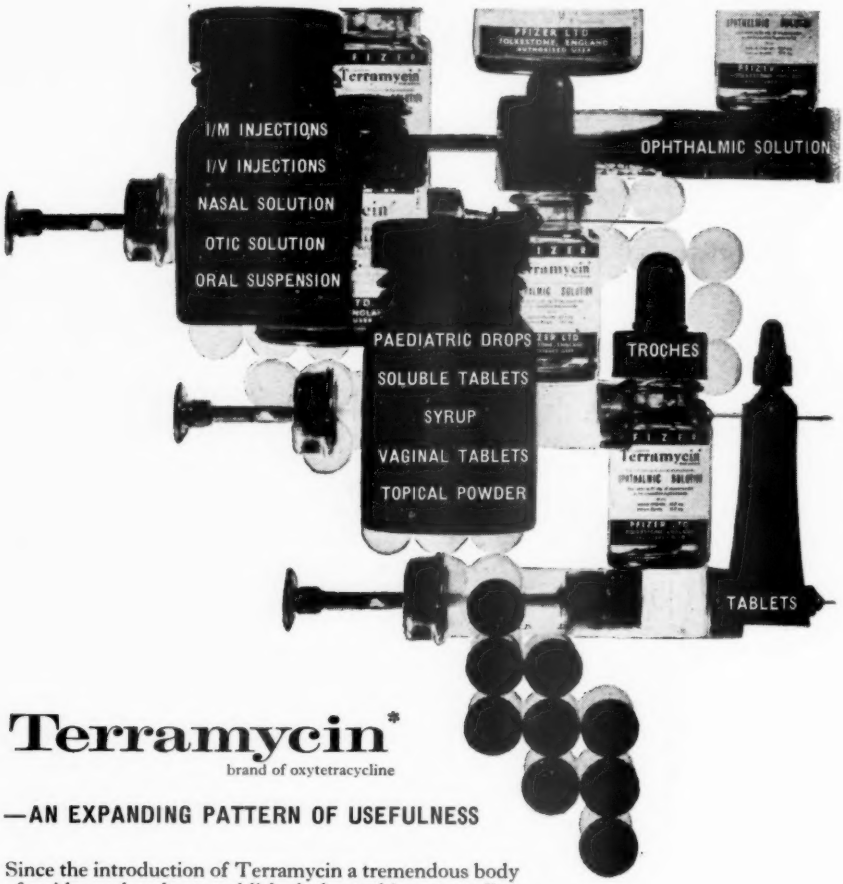
## Front-line weapon

Since its introduction, 'Ilotycin' brand erythromycin has established itself as a safe and potent oral antibiotic. Clinical experience has shown that it can play a vital part as a front-line weapon against a wide range of infections. 'Ilotycin' has a penicillin-like antibacterial spectrum, is powerfully bactericidal, has negligible effect on the normal intestinal flora, and is fully effective by mouth. It has accordingly become the logical first choice after penicillin in the treatment of common infections.

Recent reports have stressed the value of 'Ilotycin' in treating the serious complications of influenza.

The average daily dose is 1 Gm., increased in severe infections.



'Ilotycin' is available as Tablets of 100 mg. and 250 mg.; also as 'Ilotycin' Paediatric and as 'Ilotycin Glucoheptonate' Intravenous.

brand of oxytetracycline

## —AN EXPANDING PATTERN OF USEFULNESS

Since the introduction of Terramycin a tremendous body of evidence has been published about this outstanding broad-spectrum antibiotic. Today, its value is known and established in almost every type of disease where infection is a factor. Following the course of this development we have introduced a wide variety of dosage forms, so that the clinical effectiveness of Terramycin should be enhanced by convenience and acceptability of presentation.

The very bulk of the available evidence becomes almost an embarrassment to the busy practitioner who — having accepted the clinical value of Terramycin — wants a concise picture of indications, dosage, therapeutic effect and possible side effects, in some specific condition. To overcome this problem we are preparing a series of brief monographs on the use of Terramycin in specific groups of indications. The second of these, 'Terramycin in the treatment of Genito-Urinary Infections,' is now available.

President—J. A. CHOLMELEY, F.R.C.S.

[*October* 1, 1957]

THE following cases were shown:

**Early Painful Osteoarthritis of the Hip-joint.**—Mr. K. I. NISSEN.

A woman aged 50. Six months ago the vertical system of medullary blood vessels was interrupted at the intertrochanteric level by transverse forage through a small hole in the lateral cortex. The pain was relieved immediately. It is suggested that the mechanism of relief of pain is a reduction in the level of hyperæmia of the head and neck of the femur, similar to the effect produced by a McMurray osteotomy.

**Three Cases of Fractured Scaphoid, Treated by Internal Fixation with Lag Screw.**—Mr. ROY MAUDSLEY.

**Craniopharyngioma and Slipped Upper Femoral Epiphysis.**—Mr. B. J. S. GROGONO.

Female aged 18 showing signs of immaturity and retarded growth. Craniopharyngioma first diagnosed at 12 years, subsequently controlled by aspiration, partial excision and Torkilsden's short-circuiting operation for internal hydrocephalus.

Complications: Homonymous hemianopia and diabetes insipidus (controlled by pituitary snuff). Slipped left femoral epiphysis not affected by traction but fusing soundly in slipped position while opposite femoral epiphysis remains unfused.

Residual deformity of left hip but no pain.

**Four Cases of Amputation of the Fifth Ray in the Foot.**—Mr. B. J. S. GROGONO.

**Albers-Schönberg Disease Followed Since Childhood with Multiple Fractures.**—Mr. W. D. GRAHAM (for Mr. P. H. NEWMAN).

**Spontaneous Rupture of Extensor Tendon to Right Ring Finger.**—Mr. E. H. HAMBLY.

**Oblique Compound Fracture of Tibia, Treated by External Fixation with a Compression Calliper.**—Mr. W. H. GERVIS.

**Two Cases of Arthrodesis of the Hip-joint by a Modified Ilio-femoral Graft.**—Mr. A. C. BINGOLD.

**(1) Solitary Eosinophilic Granuloma of Right Ilium. (2) Solitary Xanthoma of Left Acromion.**—Mr. B. LAWSON.

**Congenital Contracture of Left Hand (? Pseudo-Dupuytren).**—Mr. B. LAWSON.

Female aged 18 months. First seen at age of 7 weeks with severe flexion contracture of middle finger and slighter of ring finger; palmar fascia adherent to thickened palmar skin with a thickened band across anterior aspect of 3rd metacarpophalangeal joint, fixed ulnar deviation of wrist. Daily stretchings, followed by "lively wire" splint. Child now also presents thickening of subcutaneous tissue of forearm extending up postero-lateral aspect of arm nearly to shoulder, and limitation of wrist and elbow movements.

**Alkaptonuria (Ochronosis).**—Mr. P. I. BUSFIELD (for Mr. G. P. ARDEN).

# Tendon Transplants in Poliomyelitis and in Obstetrical Palsy
## [*Summary*]

By JOSEPH BARR, M.D.
*Boston, Mass., U.S.A.*

**Dr. Joseph Barr,** in discussing certain aspects of tendon transplantations for anterior poliomyelitis, said that in his belief such transplantations should rarely be done earlier than sixteen to twenty-four months after the attack; by that time the patient had reached a stage of functional stability and a proper assessment of the best available surgical procedure could be made. While an accurate muscle chart was useful, he had never found this in itself sufficient evidence on which to assess the need for any particular operation. The vital factor was the functional examination and this might have to be repeated several times before all relevant factors could be evaluated. This gave time both for the surgeon and the patient to decide which was the most significant functional disability, the relief of which would be most valuable to the patient. Deformities once started tended to increase steadily throughout growth. It was important not to do tendon transplants too early because, for example, a foot which by tendon transplantation had been correctly balanced in early life might very well become unbalanced as the result of later growth. An exception to this rule was calcaneo-valgus deformity, for which early intervention was indicated and where he felt that there was still a place in a few cases for tenodesis of the tendo achillis. It was true that there was a risk of later equinus, developing as a result of this tenodesis, but the final state, as far as securing a balanced foot was concerned, was better. In the lower limb he thought there was a considerable risk of "over-bracing", certainly in the United States and very probably in other countries too. This led to disuse of the remaining muscles and was positively harmful at times.

The prerequisites of successful tendon transplantation were now well established. There must be no deformity present, or any such deformity must be corrected before operation. The transplant must carry sufficient power, the line of pull must be as direct as possible; he preferred to anchor his tendon to bone if possible. It was, of course, vital to preserve the blood and nerve supply, and as far as the question of tension was concerned, this was a matter of experience, but there should be "just enough" tension in the tendon when the joint was in the over-corrected position. Although long immobilization was not necessarily indicated, protection of the transplanted tendon must continue for a long time. He also stressed the need for expert physiotherapy and re-education if the best results were to be obtained.

He then turned to certain specific problems. Starting with the hand, for opponens paralysis he recommended the transplant of the flexor digitorum sublimis tendon of the ring finger, and said he had found it unnecessary to pass it round the tendon of flexor carpi ulnaris as a pulley; it could be freed in the palmar space and from there taken directly to metacarpophalangeal joint of the thumb. The tendon should be freed from the ring finger almost at its insertion; if a long stump were left it could become adherent and cause flexion deformity of the proximal interphalangeal joint. Even so he recommended the use of a splint to keep this finger in extension for a week or so after operation. The two slips of tendon thus obtained were sutured one to the phalanx and one to the metacarpal head; in cases where there was paralysis of the extensors of the thumb, it was important that one slip should be inserted into the extensor tendon to regain this movement.

He discussed the standard transplant of the wrist flexors into the finger and thumb extensors, recommending that palmaris longus should be passed to the thumb abductor and short extensor and both flexor carpi radialis and flexor carpi ulnaris into the long thumb extensor and the common finger extensors. The pronator teres should be inserted into the radial wrist extensors. Arthrodesis of the wrist was not popular with patients and should be strictly reserved for those cases where insufficient transplants were available. It should be done *after* any possible transplant operations.

To provide flexion at the elbow he considered the Steindler operation a good one, but recommended that the deep layer of the common flexor origin should be left intact and only the superficial layer transplanted proximally. The common extensor origin could also be transplanted proximally up the humerus if necessary, but this was a more difficult procedure.

To provide abduction of the shoulder he was willing to use any and all muscles available and had sometimes used trapezius, coracobrachialis and the short head of biceps, and the

long head of triceps all in one case. Turning for a moment to obstetrical paralyses, he recommended that for Erb's palsy a transplant posteriorly of the subscapularis tendon into that of teres minor was very helpful in providing external rotation, so that when the arm was abducted the hand could then be brought to the mouth. He considered this a better procedure than the standard Sever procedure or a humeral osteotomy.

In paralyses involving the trunk early recognition of scoliosis and adequate protection was essential; progressive cases should not be left too late but should be treated by correction and spinal fusion over a great length of the spine.

In discussing paralyses around the foot and ankle he considered that an ankle fusion alone was in many cases a most useful operation and in young children was a better procedure than the pan-arthrodesis, at least as a primary operation. A central graft passed through the middle of the lower tibial epiphysis into the body of the talus would promote fusion without interfering with the growth of the tibial epiphysis. When the peronei were going to be used as transplants into the dorsum of the foot, it was important that the peroneus brevis alone should be used if a functioning tibialis anterior was present to avoid the cocking-up of the metatarsophalangeal joint of the big toe, and if tibialis anterior were absent then peroneus longus should be used to avoid the formation of callosities under the first metatarsal head. If the tibialis posterior were going to be used, he recommended that a window should be cut out of the interosseous membrane before the tendon was passed forward to give it free passage and movement in this region; its function might be limited if it were simply pushed through a hole forced in the membrane.

In the case of quadriceps insufficiency, biceps and semitendinosus alone should be used in order to avoid the development of a back knee. Furthermore the biceps tendon should be transplanted into the patella along the medial side of the femur, which provided a more direct route and did away with the danger of lateral subluxation of the patella which not infrequently resulted from transplants of this tendon done on the outer side of the thigh. He mentioned that a flexion-abduction contracture of the hip was not due to *contracture* in the ilio-tibial tract, which from its very structure was not capable of contracting. The point was that longitudinal growth of the ilio-tibial tract did not keep pace with the growth of the bone. He had found the erector spinæ transplant a very satisfactory one in suitably selected cases.

In cases of unequal leg length in adults he had abandoned leg-lengthening as it carried too many risks, and he recommended shortening of the longer limb. Leg shortening from poliomyelitis was not a significant problem in patients who had suffered the disease after the age of 11, and before this age only if there was sufficient discrepancy in the paralysis in the two legs. From Stinchfield's work it had been found possible to predict with considerable accuracy the degree of discrepancy which would occur in any given case. From Green's tables it was possible to estimate the correct time to do an epiphyseal stapling of the distal femoral epiphysis of the longer limb, and this had in every case produced adequate equality of length. He therefore preferred epiphyseal stapling to leg shortening procedures if the stapling procedure could be done in time to give satisfactory correction.

### Discussion

**Mr. H. J. Seddon** pointed out that work in this country had shown that paralysis, as opposed to paresis, of muscle, could be considered final six months after the disease and in certain cases he considered it perfectly permissible to proceed with suitable tendon transplants done at about this time. He also considered that transplanting tendons into other tendons was an easier procedure and was perfectly satisfactory if well done. He agreed that fusion of the wrist should only be done with strong indications, and then only after suitable transplantations.

**Mr. H. Osmond-Clarke** agreed that muscle charts were quite useless as far as interpreting the type of operation which was necessary. He considered that surgical shortening of the longer leg was a better procedure than epiphyseal stapling.

**Mr. Donal Brooks** spoke in favour of arthrodesis of the shoulder in some cases. He also said that any attempt at transplants to provide shoulder abduction was useless unless external rotation power was present.

**Mr. Barr,** in conclusion, said that he would be happy to proceed with the tendon transplants six months after the disease if he was satisfied that matters were static. He believed that in most cases fusion of a joint should be deferred until the onset of adult life; it was an irrevocable procedure and the patient could then take part in the necessary decisions. He disliked fusion of the hip, which he did very rarely in cases of poliomyelitis, and it was indicated only when subluxation of the hip had occurred and was not amenable to stabilization by any other means. The transplant backwards of the origin of tensor fascii femoris he had found a useful operation in spastic diplegia, but not in cases of poliomyelitis.

[*December* 3, 1957]

# SYMPOSIUM ON THE TREATMENT OF ORGANIC SPINAL DEFORMITIES

OPENING papers were read by Mr. J. I. P. JAMES, Mr. H. OSMOND-CLARKE and Mr. R. ROAF; those by Mr. James and Mr. Roaf appear below.

**Mr. J. I. P. James** (London), opening the symposium, discussed the indications for surgical treatment. He first of all emphasized that the value of conservative treatment by exercises, spinal supports, &c., had never been objectively demonstrated, and in his own practice were not used. There was, however, one exception—the Milwaukee jacket. As applied to children too young for operation with rapidly progressive severe curves, this jacket could maintain a curve and even hold some correction during several years of growth.

## *The Indications for Correction and Fusion*

It should be emphasized that the great majority of those with scoliosis did not require operation because the natural development of most curves led to only a small deformity. However, there were a number, particularly those with paralytic curves, in whom a severe deformity would arise.

A distinction must be made between mature and immature curves. When the iliac apophyses had grown completely round to reach the posterior superior spine, spinal skeletal maturation was complete and the curve mature.

*Mature curves.*—Surgery did not affect the rotated ribs, usually the worst of the three parts of the deformity. In the fully grown scoliotic, therefore, consideration must be given to the amount of improvement available. The raising of a shoulder and the covering of a prominent hip were the only features which could be helped, and unless these were gross, surgery was unprofitable.

*Immature curves.*—Growing children with scoliosis nearly always had a progressive curve. This varied with the ætiology and with the various anatomical levels of curvature. The aim of surgery at this age was the correction and fusion of a curve in which the prognosis was known to be bad, in other words prophylaxis. The prognosis of the various types must therefore be known before surgery was decided upon.

## *Idiopathic Scoliosis*

There were two main factors affecting the prognosis of idiopathic scoliosis. First, the anatomical site of the primary curve; the higher the curve in the vertebral column the worse was the prognosis. Second, the age of onset; the earlier a curve appeared the worse it was at the completion of growth.

*Thoracic idiopathic scoliosis.*—The common pattern was a rapidly progressive right-sided curve seen in children after the age of 10. About half of these developed a curve of more than seventy degrees and would require surgery, especially if the curvature was fifty degrees or more by the age of 10 to 12 years.

In infants it was not uncommon to see a left-sided thoracic curve appear in the first three years of life and such a curve increased so relentlessly that curves of a hundred degrees were common in children of 5 to 7 years of age. Almost all required operation but a Milwaukee jacket could delay operation until the child was 10 years old. Before this age operation was considered undesirable, though real knowledge of the best age was lacking.

*Thoraco-lumbar idiopathic scoliosis.*—This rather uncommon curve only occasionally produced a severe curvature. The main feature was a prominent hip and occasionally even a small curve should be operated upon for this reason. Approximately 5% of these curves required operation.

*Lumbar idiopathic curves.*—None of these curves required operation for cosmetic reasons. Some later developed osteoarthritis sufficiently severely to produce pain and necessitate spinal fusion.

*Double primary thoracic and lumbar idiopathic scoliosis.*—The previously mentioned patterns had a single structural curve; this last group has two curves in opposite directions. The overall effect of such balanced curves is a good appearance and it is only in some 5% that each curve reaches one hundred degrees; it is this small group which may require correction and fusion. Unfortunately correction produces little or no improvement in the appearance, so the difficulty is making a decision before the deformities become severe. Since severe double curves are very uncommon this is a difficult task and fusion is therefore rarely indicated.

*Paralytic Scoliosis*

The outlook in paralytic scoliosis is very much worse than in the idiopathic type. Although the anatomical site of the primary curve is a very important factor in the prognosis, this is not the dominant one as in idiopathic curves. Another factor is the age at onset of poliomyelitis; the earlier it is the worse the final outlook. The third factor, and an important one, is the degree of muscle paralysis with imbalance between the two sides, particularly of the intercostals and lateral abdominal flexors. One other factor to be considered in paralytic curvature is the effect of severe but symmetrical trunk paralysis. This leads to backache, fatigue or instability, and fusion may be required for this independent of the cosmetic appearance.

*High thoracic paralytic scoliosis.*—This curvature has a very poor outlook; most of the curves develop more than one hundred degrees. The most serious cosmetic effect is the elevation of the trapezius line by the rotated transverse processes of the upper thoracic vertebræ; this is irreversible by correction and fusion. Surgery, to be effective, must clearly be undertaken before this occurs, and in the majority of cases, because most develop this serious deformity. The Milwaukee jacket is a very useful method of delaying operation.

*Thoracic paralytic curves.*—These behave in a fashion comparable to the thoracic idiopathic group, although commonly more severe. A child with a paralytic curvature of forty to sixty degrees at the age of 10 is certain to require correction and fusion before growth is complete, and it is therefore wise to undertake it early.

*Thoraco-lumbar and lumbar paralytic curves.*—These curves often become very gross and very ugly, but in such cases the child is often otherwise sadly crippled and the appearance perhaps does not matter so much. However, in many children the trunk instability is a handicap in walking, and fusion (including the sacrum if there are good hip flexors) is invaluable.

*Congenital Scoliosis*

This group is unpredictable. The great majority of children with congenital vertebral anomalies do not produce a severe curvature; many with hemi-vertebræ end up with minor kinks in their spine and there certainly is no indication for their removal. On the contrary, however, some children with congenital defects develop a curvature more severe than that seen from any other ætiology. This is particularly common when there are multiple defects over a length of six to ten vertebræ. The only way to assess a congenital scoliosis is by continued observation. Surgical intervention is called for if there is clear indication of progressive deterioration.

*Neurofibromatosis.*—10% of children with neurofibromatosis, Von Recklinghausen's disease, develop curvature. These curves are characteristically short, commonly involving five vertebræ; they are usually in the thoracic region. In the later stages kyphosis is not infrequent. The prognosis is such that all should have a prophylactic correction and fusion.

Mr. **Robert Roaf** (Oswestry):

*The Treatment of Resistant Scoliosis*

From the clinical aspect, there are four main types of scoliosis. Firstly, there is a relatively benign type which does not require any specific orthopædic treatment. This group will comprise most lumbar curves, most "double-primary", i.e. thoracic and lumbar curves, some late onset thoracic and thoraco-lumbar curves and congenital curves in which the anomaly is one or at most two hemi-vertebræ. The above curves do not usually produce severe deformities, i.e. the deformity is cosmetically acceptable and there is no serious distortion of the lungs, heart or great vessels.

By "cosmetically acceptable", I mean that the shoulders are level, a plumb line from the vertebra prominens falls within three-quarters of an inch of the gluteal cleft, and the rib hump can be masked when the patient is clothed. Recent work in the U.S.S.R. (Vilhovoy and Boyanovsky, 1957) suggests that a right-sided scoliosis carries a much worse prognosis than a left-sided scoliosis as far as distortion of the great vessels and aortic obstruction are concerned. Severe skeletal changes are compatible with satisfactory appearance and good function. This group may need encouragement and advice concerning their work, hobbies, games, dress and hair-style, but do not require splints, plasters, operations, prolonged rest or remedial exercises.

The second group consists of patients in whom the deformity is progressive and will become severe if left untreated but the curve can be corrected by conservative means, e.g. an Abbott or a Risser type of jacket, after which spinal fusion will hold the spine in satisfactory alignment.

The third group includes the flail spine in which the deformity is relatively slight in recumbency or can be easily corrected, but in whom there is gross instability and a tendency

to collapse. Such patients must either wear a cephalo-pelvic distraction brace of the Milwaukee type (Blount, 1949) or have an extensive spinal fusion.

The last group consists of patients in whom the deforming forces are very strong and in whom either correction by conservative means alone will be very difficult or, after correction and fusion, relapse will occur.

The present paper is concerned with this last group which represents only a small but important minority of all patients with scoliosis. In this group, the deforming forces are strong either because there is gross asymmetry of growth potential—as with many hemi-vertebræ, extensive vertebral hemi-fusion, multiple fused ribs or other multiple congenital anomalies, or because there is marked vertebral rotation. Whatever may have been the original cause of the deformity, once there is marked rotation deformity certain inevitable consequences result which must tend to increase the deformity (Roaf, 1958).

Firstly, the line of the centre of gravity falls to one side of the rotated vertebral bodies, tending to increase lateral curvature and inhibit growth potential on the concave side; also the longitudinal fibres of the erector spinæ muscle, whose normal action is to push the vertebræ forwards, are no longer opposed by gravity. Secondly, the long spinal muscles push the rotated vertebral bodies sideways and, as has just been pointed out, this lateral movement is unopposed by gravity. Thirdly, the balance between the deep oblique fibres of the erector spinæ muscle on the two sides is upset and their action now tends to increase the deformity. Fourthly, the deformity of the ribs is such that the respiratory movements tend to increase the deformity. Normally, the rib heads exert a balanced pressure on the sides of the vertebral bodies. In scoliosis with rotation, the pressure of the ribs on the convex side is exerted posterior to the axis of rotation, and coming on the concave side it is anterior to the axis of rotation; thus, a couple of forces is created which tends to increase the deformity at every breath.

These principles are exemplified in the treatment of four types of scoliosis—infantile scoliosis, lumbar scoliosis with lumbo-sacral instability, and thoracic and thoraco-lumbar curves with marked rotation.

*Infantile scoliosis.*—Some of these improve spontaneously; others become rapidly worse. In two children in whom the curves were becoming worse, I have managed to reverse the process by excising the spinous processes (Figs. 1A and B). The rationale of this procedure is to eliminate the rotatory action of the deep oblique fibres of the erector spinæ muscle. Clearly, such a procedure is only likely to succeed in the comparatively early case where the structural bony changes are still minimal. If there are already bony changes, more radical measures will be required (*see* following pages).

A B

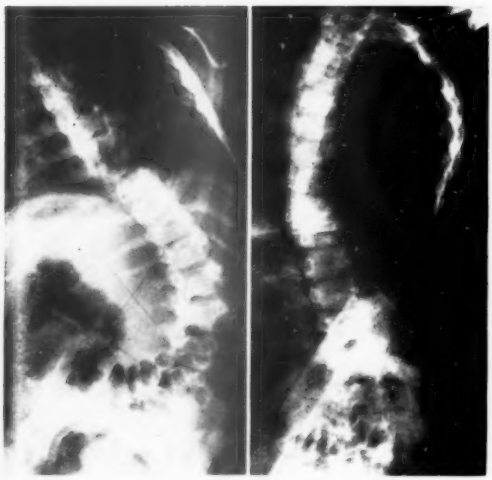
FIG. 1A.—Progressive infantile scoliosis. Age 2.

FIG. 1B.—Same patient three years after excision of spinous processes.

A B

FIG. 2A.—Lumbar scoliosis with lumbo-sacral obliquity

FIG. 2B.—Same patient after stabilizing the lumbo-sacral region with an ilio-lumbar bone strut.



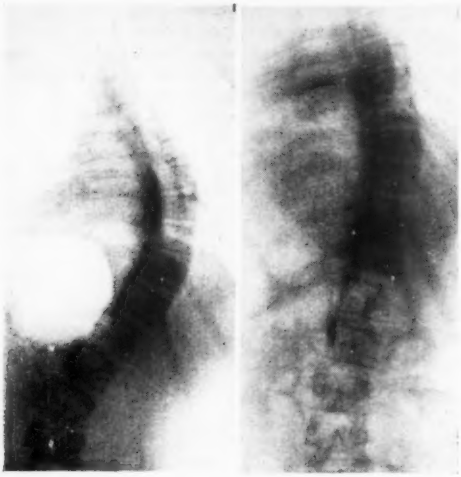
*Lumbar scoliosis with lumbo-sacral obliquity.*—Lumbo-sacral obliquity as opposed to pelvic obliquity makes correction of a lumbar curve very difficult, as the corrective force usually tends merely to increase the lumbo-sacral tilt: it is notoriously difficult to apply a corrective force directly to the apex of a true lumbar curve. It is worth noting that these curves are much uglier than ordinary lumbar curves as the whole trunk is shifted to one side. I have sometimes found it necessary to stabilize the lumbo-sacral joint with an ilio-lumbar bone strut before correcting the lumbar spine (Figs. 2A and B).

*Thoraco-lumbar scoliosis with marked rotation.*—Thoraco-lumbar scoliosis without marked rotation is a comparatively easy problem; the curve usually remains relatively mobile—at any rate for some years; conservative control during the growing period is relatively easy; conservative correction by some form of three-point pressure jacket is usually successful. After fusion, there is relatively little tendency to relapse. By contrast, if there is marked rotation the curve tends to become fixed, control and correction are difficult, and relapse after fusion is common. In fact, in the presence of marked rotation posterior interlaminar fusion in the growing period may be actually harmful, as the neural arches are tethered by the fusion but the bodies continue growing; thus the "lordosis" is increased and, owing to the vertebral rotation, this means that the vertebræ at the apex of the curve are further displaced from the mid-line.

In young patients, treatment by derotating appliances is indicated. In more advanced cases, where the curve is getting worse in spite of treatment, operative mobilisation of the spine may be required. In moderately severe cases, the main bony deformity is an asymmetry of the neural arches which are larger in all dimensions on the convex side. Adequate mobilization of the spine and correction of the deformity may be obtained by excising the interlaminar joints on the convex side.

In very severe cases, especially where the onset of deformity is early in life, a more radical procedure is required, namely multiple wedge resection of interlaminar joints and intercorporeal joints (Figs. 3A and B). This is a development of and an improvement on the original operation of massive wedge resection described by the author in 1955 (Roaf, 1955). It has the further advantage that it can easily be combined with a partial lateral vertebral epiphysiodesis by packing cancellous bone into the wedges in the bodies. If the epiphysiodesis is successful, further growth tends to correct the deformity.

Longitudinal traction and forced side bending are comparatively ineffectual methods of trying to correct these rigid curves, although they are useful where the kyphotic element predominates. Usually all that happens is that the mobile ends of the curve are corrected but the fixed central portion is unaffected, and the deforming forces which cause relapse are as strong as ever.



A B

FIG. 3A.—Severe progressive scoliosis due to multiple hemi-fusion. Previous conservative and operative attempts at correction had failed.

FIG. 3B.—Same patient after multiple partial epiphyseal resection.

*Thoracic scoliosis.*—Here the outward deformity is usually mainly due to the "rib hump". In the younger age group and in the less severe deformities, the curve can be controlled by either a jacket of the Abbott type or a removable splint which works on the same principle. The fundamental principle is *forward* pressure on the posterior chest wall on the convex side, *backward* pressure on the anterior chest wall on the concave side, and space for the posterior chest wall on the concave side to expand.

There is, of course, a limit to the force which can be applied to the vertebral column by external splinting. First, the skin of the trunk is relatively intolerant of continuous pressure; secondly,

A B

FIG. 4A.—Thoracic curve after attempted conservative correction.

FIG. 4B.—Same patient after lateral epiphysiodesis.

the ribs are more pliable than the vertebræ. A few years ago, I tried to derotate scoliotic spines by applying wire traction to the ribs on the concave side. I found it fairly easy to pull out the ribs and reduce the chest wall concavity but this had very little effect on the vertebral rotation.

The advantage of the Abbott principle is that pressure is intermittent, increasing with inspiration and diminishing with expiration. Such appliances must be worn for a long time and the patient must practise deep breathing. As the treatment may extend over a number of years, a removable splint is often preferable to a plaster jacket, but the underlying principle is the same. In older patients correction is more difficult, and operative mobilization of the spine as described previously may be required. (Figs. 4A and B). Finally, for mature patients with severe deformity, there are two purely cosmetic procedures which are often much appreciated by the patients, viz. partial excision of the scapula and multiple costo-transversectomy.

**Mr. Denis Browne** (London), referring to infantile scoliosis, said that, in his opinion, the cases which had been described were unnecessary tragedies which could be avoided if the condition were diagnosed and efficiently treated in its earliest stage. In many respects it resembled congenital dislocation of the hip in that both conditions originate before birth, can be diagnosed in the newborn, and at this time in this country are overlooked in the vast majority of cases till the child has walked.

Though the scoliosis in the neo-nate looked very slight, its nature could be demonstrated by "triptych" X-rays which he showed, taken with the baby first lying at ease, and then bent to either side. These demonstrated the fixed nature of the scoliosis, and differentiated it from the simple wriggles so often confused with it. He suggested that orthopædics began before birth, and that the pathology of such conditions as this kind of scoliosis, congenital dislocation of the hip, talipes, and arthrogryposis would not be understood till more study was made of intra-uterine conditions. He also illustrated a splint which allowed free movement of a baby while reversing the curve of the spine, in a way that could not be done by a plaster bed.

## Polyposis Intestini [*Abridged*]

### PRESIDENT'S ADDRESS

By HENRY R. THOMPSON, M.A., M.B., F.R.C.S.

#### DESCRIPTION OF THE DISEASE

POLYPS may arise anywhere in the intestinal tract. They may be solitary or multiple and may result from adenomatous proliferation, inflammation or parasitic disease.

In the large intestine, multiple polypi may develop as a result of bilharzial infection or as a complication of ulcerative colitis, and the latter may be confused with adenomatous polyposis. The large intestine is the commonest place for adenomatous polypi to occur. They may appear singly, in groups of two or three, sometimes close together and at other times in widely-separated regions of the bowel, or there may be many thousands of polyps as in hereditary familial polyposis.

The question frequently arises of how many polyps must be present before the diagnosis of polyposis can be made. There is no numerical answer. The diagnosis must be based on a critical assessment of the patient's age, family history and the number and distribution of polypi. For the middle-aged patient with no family history of polyposis who has a few scattered polypi in the large intestine, the term "multiple adenomata" should be used rather than "polyposis".

The disease is characterized by hyperplasia of the glandular epithelium in the mucous membrane of the colon and rectum, resulting in the development of multiple tumours (Fig. 1). The number and distribution of the polypi vary considerably in different families and

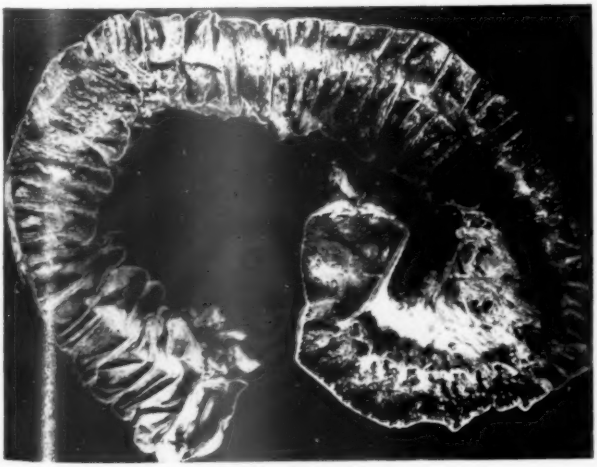

FIG. 1.—Polyposis.

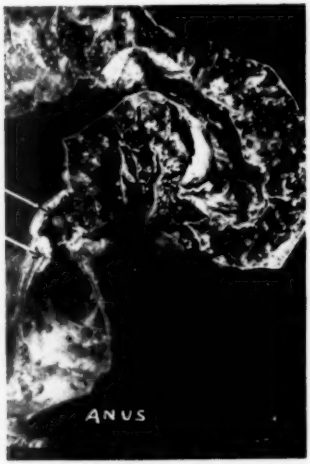

FIG. 2.—Polyposis with carcinoma.

obviously depend upon the length of time the disease has been developing before diagnosis. These tumours may be sessile and the size of a pin's head, or larger pedunculated tumours up to an inch in diameter. Of the recorded cases at St. Mark's Hospital, not one has been free of polyps in the rectum. This I regard as an important point in differential diagnosis. Moreover, although the literature states that polypi are present in the stomach in 5% of cases, I am not aware of a case of polyposis at St. Mark's having polypi elsewhere in the gastro-intestinal tract. Here I must add that gastroscopy and barium meal do not constitute part of the investigation carried out on our patients.

I should like to draw attention to a syndrome which, although reported in 1921, has remained relatively undiscussed until the last twelve years. I refer to the condition where multiple polypi occur throughout the gastro-intestinal tract, but predominantly in the small intestine. It is associated with pigmented spots on the buccal mucosa, lips and face, and sometimes on the digits of a dark-complexioned patient. The condition usually presents as an intussusception of the small intestine in the second decade of life. It is referred to as Peutz Jegher's syndrome. The condition has a familial incidence and, like polyposis coli, is believed to be transmitted as a Mendelian dominant. The clinical manifestations of the disease, however, are so different from those of polyposis coli that, apart from its genetic tendencies, it appears to be a different disease.

Although diffuse polyposis has been reported in an infant, polypi start to develop, as a rule, about the age of puberty. They give rise to symptoms at the age of 20, and fifteen years after the onset of symptoms the polypi start to turn malignant. Cancer will develop by the age of 35, some twenty-five years earlier than the development of carcinoma of the large intestine in the general population (Fig. 2).

The first symptom is diarrhœa and this is unlikely to start until a considerable number of polypi have developed. At its onset it is so slight and its progression is so slow that changes in stool consistence and bowel habit may go unnoticed by the patient. It is remarkable the number of polypi that can develop and the extent of the bowel involved in a patient who denies any symptoms. Eventually, the increasing diarrhœa, with the occurrence of hæmorrhage and mucous discharge, interferes with the patient's daily life and leads to deterioration of his general health.

## Genetics

Polyposis coli is a hereditary disease and is passed on through families from one generation to the next. The units of hereditary transmission are genes which occupy fixed positions in the chromosomes and are probably large, single protein molecules. It is at present believed that hereditary diseases are the result of gene mutations. Some of these diseases, such as hæmophilia, are present at birth. Polyposis, on the other hand, develops at puberty—a characteristic it shares with hereditary optic atrophy. Polyposis affects both males and females and can be transmitted by both sexes but only those who have inherited polyposis can transmit it to the next generation. Half of the children in such families will inherit the disease.

Investigation of a family with this disease starts with the diagnosis of polyposis in an affected member. At the time of diagnosis enquiries may produce evidence of the disease in other members of the family. The preliminary interviews with the family should be made with the object of selecting a "collaborator", embued with what Dr. C. Dukes has so aptly described as the "tribal outlook", or someone who knows all the family affairs—usually a "she".

Once a collaborator is established, there is a chance of keeping in contact with family members.

## Treatment

The problem of the treatment of a case of polyposis involves the treatment of an individual with the disease, and the little group or community of people that constitute the family. It is essential that the treatment of the first sufferer in a family should, if possible, be free from anxiety and complications. This is the talisman for winning the confidence of the family itself.

The only effective treatment known at present is surgical removal of the large intestine. This is commonly practised in one of two ways—total removal of the large bowel with permanent ileostomy, or subtotal removal of the large bowel with preservation of a rectal stump and restoration of continuity of the bowel.

(1) *Total removal of the large bowel.*—The disadvantage of this operation is that the patient is left with a permanent ileostomy with the recurring trouble of ileostomy appliances, and the risk of ileostomy complications, as well as the complications that may arise from excision of the rectum, such as impotence in the male. The advantages are that it removes all risk

of malignancy, and check-ups are not required. It is the only treatment if a carcinoma is present in the rectum, and indeed many consider that it is indicated should malignancy be present in any part of a colon affected with polyposis.

(2) *Preservation of the rectal stump.*—The advantages of preserving continuity of the bowel are obvious. The disadvantages are the risk of malignancy and the necessity of a six-monthly check-up on the rectal stump for the rest of the patient's life. Admission to hospital may be required for fulguration and a second major operation may be necessary to remove the rectum.

What is the risk of malignancy developing in the rectal stump? Light can be thrown on this subject in two ways—from our knowledge of where carcinoma occurs in malignant polyposis, and from the number of cases that subsequently develop a carcinoma in the retained rectal stump.

Of 70 patients operated on at St. Mark's Hospital for polyposis, 30 had already developed a carcinoma of the large bowel at the time of treatment. In 23 of these 30, malignant change had taken place in the rectum. From this it would appear that the rectum is the commonest place for a carcinoma to develop and it is this segment of the large bowel, if any, that should be removed.

A statistical study of the occurrence of a carcinoma in the rectal stump following ileo-rectal anastomosis is at present not possible because there are no sufficiently long follow-up records available after this operation. Of cases treated by preservation of the rectum at St. Mark's, 3 are known to have developed a carcinoma in the rectal stump, two, sixteen and twenty-one years after operation; a case of Mr. H. Edwards' developed a carcinoma ten years later.

The literature would suggest that at the moment the incidence is between 5% and 8% but with the passage of time I feel sure this figure will increase.

The argument in favour of retaining a rectal stump and restoring continuity of the bowel rests on the supposition that if a carcinoma develops it will start as a malignant change in an adenoma and that this change can be prevented by keeping the rectal stump free from polypi by six-monthly examinations and fulgurations. Against this it must be pointed out that a carcinoma may develop *de novo* from rectal mucosa without the intervening stage of a polyp; and either patient or surgeon may default on the six-monthly check. At these follow-up examinations the rectum frequently contains fæcal material and a thorough examination is not possible unless the bowel is prepared. Moreover, a break in supervision may result from the surgeon retiring or dying. It is easy to talk about regular checks and keeping the rectal stump free from polyps but it is a different matter to achieve in practice.

Thus it would appear that the more radical operation is safer for the patient and easier for the surgeon. There is, however, a human side to this problem. First, patients with polyposis are young people, some of them without symptoms. A surgeon needs considerable powers of persuasion to coax such people to submit to a permanent ileostomy with all the adjustments and changes in relationship that this entails. One does not need a vivid imagination to understand a young girl's fear that a man's encircling arm would encounter an ileostomy bag. The chances of marriage are reduced for a person with an ileostomy although at least two cases come to mind where young girls with ileo-rectal anastomoses have married and had children.

The choice lies between a normal life in one's "salad days" with the risk of cancer eventually developing in the rectal stump to shorten the normal expectation of life—contrasted with an ileostomy with its restrictions, but with the chance of a normal expectation of life. It is my experience that youth will accept the risks of an ileo-rectal anastomosis in preference to the security of an ileostomy.

An attempt at a compromise can be found in the ileo-anal operation, or anal ileostomy. In this operation, the muscle walls of the rectal stump are retained but the mucosa is removed and replaced by a length of ileum.

## Operative Details

I now propose to discuss the three operations practised to-day in the treatment of polyposis of the colon.

(1) *Proctocolectomy.*—This is best done in one stage and can be expeditiously performed by two surgeons working simultaneously, with the patient in the lithotomy Trendelenburg position. The time required to complete such an operation need not be more than an hour and a quarter. The patient will be ready to leave hospital in twenty-five days.

(2) *Colectomy and ileo-rectal anastomosis.*—This resolves itself into three phases:

(*a*) clearing the rectal stump of polypi;

(*b*) excising the colon and anastomosing the ileum to the rectum;

(*c*) subsequently keeping the rectum free from polyps.

The first phase is best managed in a series of monthly fulgurations, systematically and deliberately ridding the rectum of polypi to a distance of 15 cm. from the anal margin. The second phase is again best performed in the lithotomy Trendelenburg position. The advantage of this position is that an assistant can pass a sigmoidoscope from below after the rectum has been transected and the rectal mucosa can be carefully searched for residual polypi which should be fulgurated (Figs. 3, 4). The ileum should be divided as close to the

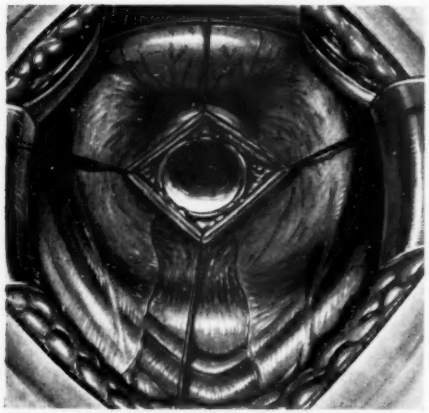

FIG. 3.—Abdominal view of sigmoidoscope passed into rectal stump, preparatory to fulguration of residual polypi.

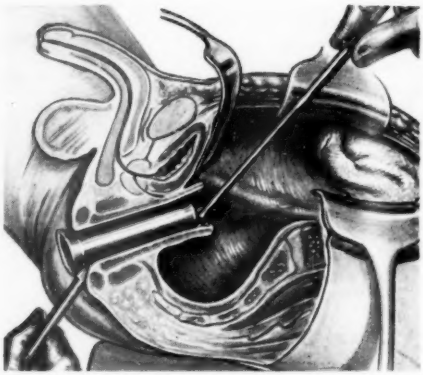

FIG. 4.—Combined clearing of rectal stump of residual polypi.

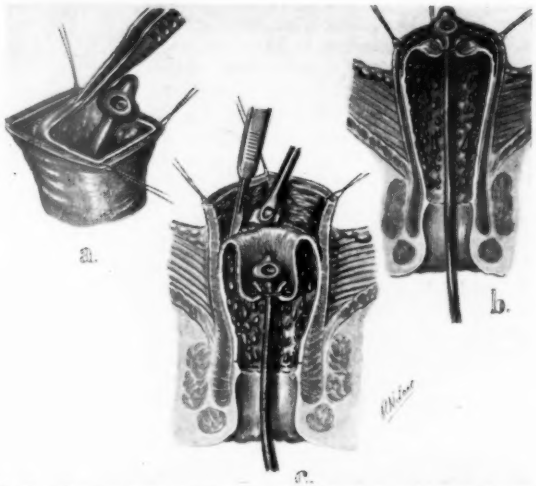
cæcum as possible for not only does it widen out near the ileo-cæcal valve, but subsequent function seems better if this portion of ileum is preserved. There is always disparity in size between the smaller ileum and the larger rectum but an end-to-end anastomosis can usually be achieved by careful "tailoring". An alternative and satisfactory procedure is to anastomose the side of the ileum to the end of the rectum, thereby perhaps achieving a wider stoma but adding the risk of a sutured blind end. From the point of view of subsequent examinations and the risk of malignant change, obviously, the shorter the rectal stump the better. I prefer to divide the rectum 2·5 cm. above the peritoneal reflection and leave a rectal stump of some 10 to 12 cm. The function of such an ileo-rectal anastomosis is satisfactory. In the months after operation the motions are loose and the bowels are open five to six times a day with an occasional action at night. This settles down and the patient finally has two formed motions in twenty-four hours.

(3) *Ileo-anal anastomosis.*—This procedure is the same as for an ileo-rectal anastomosis except that, following division of the rectal stump, the rectal mucosa is dissected or "cored out". In this procedure two points are of assistance: (1) submucosal injections of saline in adrenaline (20 minims 1/1,000 adrenaline in 4 oz. saline), and (2) to secure the necessary tension in the submucosal stripping plane a catheter is passed up the rectum from below. The cut edge of the mucosa is tied to the end of the catheter and the mucosa is pulled down as it is dissected out. When the mucosa has been removed the ileum is threaded through the remaining muscular tube and sutured to the anal canal. The lithotomy Trendelenburg position is essential for the use of the catheter and for the suturing of the ileum to the anal canal (Fig. 5).

(Details were given of a boy of 17 and a girl of 16, whom the speaker treated by an ileo-anal anastomosis, who were followed up for four years.)

Cases with satisfactory function following ileo-anal anastomosis have been reported in the literature, notably by Devine and Webb, and this method merits trial where indicated.

In my cases it was considered that the ileum separated from the anal canal and retracted to the top of the rectal stump where it was firmly held by interrupted seromuscular sutures. The bare rectal tube finally became epithelialized (Fig. 6).



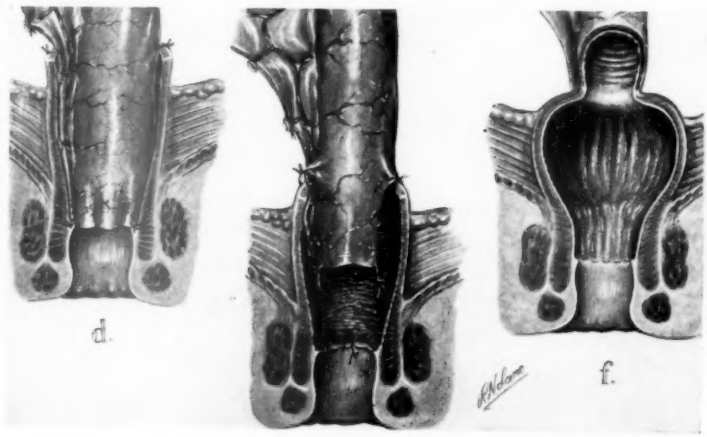


FIG. 5.—Method of coring out anal mucosa. a, Catheter inserted in rectal stump. b, Cut edge of mucosa tied to catheter. c, Traction on catheter aiding dissection of mucous membrane.

e.

FIG. 6.—Diagrammatic representation of probable result of author's two cases of ileo-anal anastomosis: d, anastomosis completed. e, breakdown of anastomosis and retraction of ileum to top of muscular rectal stump. f, re-epithelialization of rectal stump.

It is more than a coincidence that each of these cases has had a post-operative intestinal obstruction. This complication is unpleasantly frequent in abdominal operations where raw areas and ligated pedicles are left in all four quadrants of the abdomen. Because of the adherence of retained omentum to loops of small intestine, I think that it is better to remove it

I would here like to give credit to Dr. Cuthbert Dukes, for it is mainly due to his efforts and organizing ability that 57 families, embracing 700 members (250 affected by

polyposis) have been documented at St. Mark's, and his papers on the subject stand out as landmarks.

[*January* 8, 1958]

**Ileo-Cæcal Tuberculosis.**—H. R. THOMPSON, F.R.C.S., and B. C. MORSON, D.M.

Mrs. E. D., aged 71.

*History.*—Admitted to hospital with subacute intestinal obstruction after one month's history of indigestion, diarrhœa and loss of weight. No family history of tuberculosis.

FIG. 1.—Specimen showing ileo-cæcal tuberculous ulceration. Patient Mrs. E. D., aged 71.

Operation revealed a constricting growth of the ileo-cæcal region with enlarged regional lymph glands. Liver clear. Right hemicolectomy with end-to-end anastomosis.

*Pathology Report.*—Terminal ileum with the cæcum and ascending colon (Fig. 1). The terminal two inches of ileum and ileo-cæcal valve show ragged ulceration. The ileo-cæcal lymph glands are moderately enlarged and a part of the surface of the mesentery has a granular appearance.

*Histology.*—Sections show numerous caseating giant cell systems in the bowel wall. The regional lymph glands also contain similar tissue. Part of the surface of the mesentery is covered by miliary deposits.

Sections stained for tubercle bacilli show large numbers of organisms in the bowel wall but only a few in the regional lymph nodes.

**Two Unusual Cases of Recto-sigmoid Carcinoma with Bladder Involvement.**—A. N. SMITH, F.R.C.S. (for H. R. THOMPSON, F.R.C.S.).

I.—Mr. J. S., aged 22, agricultural student, was admitted to hospital on 17.9.57, with one year's history of diarrhœa with blood and mucus in the stools, loss of weight and severe dysuria. *Sigmoidoscopy* showed a carcinoma at 11 cm. Biopsy proved this to be a

FIG. 1.—Specimen of advanced carcinoma of rectum invading base of bladder and prostate.

adenocarcinoma of average grade of malignancy. *Cystoscopy* showed a bullous cystitis and extrinsic pressure on the vault of the bladder. *Laparotomy* disclosed four carcinomas in the large bowel—in the cæcum, transverse colon, recto-sigmoid and rectum. The recto-sigmoid lesion was attached to the bladder and left ureter with a recto-vesical fistula. Procto-colectomy and ileostomy (Mr. H. R. Thompson and Mr. H. E. Lockhart-Mummery) with partial cystectomy and ureteroureteric end-to-side anastomosis was performed. The patient made a satisfactory recovery with good function on an I.V.P. and a blood urea of 22 mg.%.

II.—Mr. H. H., aged 52, a sewerman, had a six months' history of diarrhœa and dysuria. He had a carcinoma of the rectum, lower edge at 5 cm., spreading down from the upper rectum and involving the prostate and bladder. Average grade adeno-carcinoma (Fig. 1). Excision of the rectum with pelvic clearance and the formation of an ileal bladder was performed (Mr. H. R. Thompson and Mr. H. E. Lockhart-Mummery). His condition was satisfactory on discharge from St. Mark's Hospital. His blood urea was 28 mg.%.

**Diverticulitis of Colon.**—BRUCE BOMFORD, F.R.C.S. (for HAROLD DODD, F.R.C.S.).

Mrs. K., aged 52. She had not walked since the age of 4 years when she had poliomyelitis affecting both legs.

*Present complaint.*—Spasms of pain in left lower abdomen with constipation for six months.

*On examination.*—Mobile mass in left iliac fossa. Opaque enema not retained; normal pyelogram; Hb 52%.

*Operation.*—Resection of mass from pelvic colon with end-to-end anastomosis.

*Specimen.*—Chronic abscess cavity encircling colon with easily seen fistulous communication to the lumen.

*Discussion.*—Case showing one of the several presentations of diverticulitis, e.g. mass clinically suggesting neoplasm. Other clinico-pathological types mentioned included acute inflammatory mass, fibrosis with intestinal obstruction and massive hæmorrhage.

**Crohn's Disease and Colitis.**—C. I. COOLING, F.R.C.S. (for RONALD W. RAVEN, O.B.E., F.R.C.S.).

A subtotal colectomy specimen was shown from a girl of 20 with a history of attacks of abdominal pain and diarrhœa for ten years. The barium studies suggested a diagnosis of Crohn's disease of the colon with an internal fistula.

The specimen revealed marked thickening of the terminal ileum with macroscopic features typical of Crohn's disease, but in the ascending and transverse colon there was extensive ulceration with pseudopolypoidal mucosa, appearances typical of ulcerative colitis. Histological preparations revealed giant and epithelial cells in granulomatous follicles as in Crohn's disease.

A comparable colon specimen of typical ulcerative colitis from a girl of 19 also showed follicles in the wall of the bowel with numerous giant cells present. Discussion on the relationship between the two diseases then followed.

**Crohn's Disease of the Rectum.**—H. W. A. BARON, F.R.C.S.

Mrs. I., aged 68.

The diagnosis of Crohn's disease in this elderly woman was made by biopsy. She presented with a two months' history of diarrhœa with slime. There was a palpable infiltrated lesion in the rectum. Sigmoidoscopy showed a stricture at 13 cm. and a barium enema showed a filling defect suggesting carcinoma. Her symptoms completely settled down without treatment. She now has one normal stool a day but despite this, changes of

granular proctitis, which were not present when she was first seen, have now developed in the rectum below the stricture. No evidence of tuberculosis was found on full investigation. A guinea-pig was inoculated with the biopsy material and no macroscopic or microscopic evidence of tuberculosis found although every organ and the inoculation site were sectioned.

**Ano-rectal Melano-sarcoma.**—FRANK FORTY, F.R.C.S.

H. H., female, aged 65.

*History.*—Painful swelling in right groin for three days.

*On examination.*—Enlarged glands in both groins. At anus several discrete firm purplish polypoid nodules extending towards the rectum and with black pigmentation spreading diffusely into the adjacent peri-anal skin.

*Operation* (17.12.57).—Abdomino-perineal excision of rectum and bilateral removal of inguinal glands. There were no obvious intra-abdominal metastases. Uneventful recovery.

Microscopically the primary growth and the inguinal glands all showed malignant melanoma with numerous mitoses and much pigment.

*Comment.*—A rare condition with a bad prognosis.

Dukes and Bussey (1947) reported 2 cases and Raven (1948) reported 3 cases, and reviewed the literature which at that time recorded only about 100 cases.

RAVEN, R. W. (1948) *Proc. R. Soc. Med.*, **41**, 469.

**Lymphosarcoma of Rectum.**—H. GORDON UNGLEY, F.R.C.S.

Mrs. B., aged 66. Admitted to Gordon Hospital, 8.5.57.

This patient presented with a feeling of incomplete evacuation of the bowels for twelve months, with occasional recent bleeding. No loss of weight.

A broad, pedicled swelling was palpable 5 cm. from the anus. Proctoscopy confirmed a sessile polyp, $5 \times 2{\cdot}75$ cm., covered by smooth but invaded mucosa.

Biopsy revealed it to be a lymphosarcoma but, unlike most of these tumours, there was no palpable induration extending up the bowel from the tumour, nor was there other evidence of dissemination.

It seemed, therefore, that this was a case available for treatment much earlier than is usual and, with a radical operation, perhaps a cure might be achieved. At the abdomino-perineal excision in May 1957 there was, in fact, no evidence of extension or dissemination of the growth.

The tumour consisted of sheets of lymphocytes without follicular arrangement invading and ulcerating the mucosa and submucosa but not involving muscle coats. Occasional mitoses were present. Because of its structure and pattern this tumour must be considered a lymphosarcoma.

In the lymph nodes examined the remains of follicles could be seen and the pulp was filled with mature lymphocytes and it was impossible to say whether this was metastatic infiltration or not.

**Polyposis Coli with Several Areas of Carcinomatous Degeneration.**—R. V. COOKE, Ch.M.

S. C., male, aged 50.

Admitted to Bristol Royal Infirmary, 16.11.57.

*History.*—He was well up to July 1957, when he noticed blood *per rectum* and occasionally slime. He had lost almost one stone in the last three months, but otherwise felt fit. He had never had any intestinal symptoms before this, except that his bowel movements had always been rather loose, and that twelve years ago he had passed a few blood-stained motions which lasted for one or two days only.

*On examination* (18.11.57).—Multiple polyps from the anal margin up to 20 cm. Harder nodules were palpable on the posterior wall of the rectum 2·5 cm. from the anus, and one hard mass a few inches higher up.

Biopsies were taken from four polypi. All proved malignant and showed well-differentiated adenocarcinoma. No signs of inflammation or ulcerative colitis or dysentery.

*Barium enema.*—Extensive polyposis of the left half of the colon to the anal margin with two greater irregular filling-defects on the posterior wall of the rectum and at the junction of the descending colon and sigmoid, these being the malignant degeneration of the polyps. From the X-rays it looked as if most of the transverse colon and the ascending colon were normal.

*Abdomino-perineal excision of rectum and removal of descending colon* (28.11.57).—Further resection deferred because much time was required to mobilise a growth in the pelvic colon which had obstructed the bowel so that the proximal colon was full of fæces.

A colostomy was made through the abdominal incision.

Following the operation he progressed, although the transverse colon at the colostomy was crowded with polypi.

*Pathological report.*—"The specimen shows papillomatosis (polyposis) of the whole colon. There is a carcinoma (6×3·5 cm.) 2 cm.; and another (5×6 cm.) 6 cm.; and a small ulcer also probably malignant 8 cm. above the anal margin. The neoplasm is a Grade II type adenocarcinoma which extends beneath the normal mucosa and is invading the muscle coats but did not reach the serous coat. The lymph gland did not show evidence of malignancy. The rest of the polypi were the ordinary ones seen in congenital multiple polyposis."

On 6.1.58 the remainder of the transverse colon and the ascending colon was excised. A proximal right transverse colostomy had to be abandoned, since there were polypi everywhere. The ascending colon and cæcum were studded with innumerable polypi. The appendix was unaffected and none was felt in the small bowel.

*Remarks.*—This case was shown as complementary to our President's address on Polyposis Coli. It merits reporting in view of the age of the patient (50) and that he had lived fifty years with so few symptoms. We were unable to find a case older than 43 in the literature. In the discussion Dr. Cuthbert Dukes agreed that the specimen with many malignancies was typical of familial polyposis coli. The absence of other cases in the family was interesting but, he said, the disease must have a fresh beginning somewhere.

It was a pity that the rectum had to be sacrificed, but its malignancy extended too low to preserve it. The man seemed undistressed by his ileostomy and is about to return to work (February 7, 1958).

*Comment.*—This patient was the only member of his family of 5 brothers and 4 sisters to be affected. His father died at 51 years of chronic hepatitis. His mother died aged 50, of some other disease. The patient's grandparents were not affected but the family was known to have "liver trouble".

**Complete Rectal Prolapse Following Operation for a Tumour of the Cauda Equina.**—E. C. B. BUTLER, F.R.C.S.

Woman, aged 33.

1947: Laminectomy and removal of neurofibromata from cauda equina (Mr. D. W. C. Northfield).

Following this operation: Gradual onset of complete rectal prolapse and incontinence of urine. The latter was treated successfully by Professor V. W. Dix.

February 1953: Admitted to the London Hospital with enormous rectal prolapse.

*Laparotomy* (11.2.53).—Pelvic colon and rectum mobilized, with excision of peritoneal pouch between rectum and vagina. Recto-sigmoidectomy carried out from below, about 1 ft. of bowel being removed. The pelvic floor was reconstituted at a higher level. Abdomen closed.

One week later patient had a severe secondary hæmorrhage, emergency colostomy was performed, which was closed five weeks later.

Patient has been well for four years and has had no recurrence of the prolapse.

Last year she became pregnant and had a Cæsarean section.

**Pneumatosis Cystoides Intestinalis.**—HAROLD C. EDWARDS, C.B.E., M.S.

Man, aged 52. In 1943 perforated duodenal ulcer repaired, since when he has suffered recurrent attacks of duodenal ulcer pain. A barium meal in 1953 showed a stenosing duodenal ulcer. A "straight" X-ray of the abdomen showed gas under the right dome of the diaphragm.

*Operation* (10.7.53).—Many thin-walled transparent cysts under the serous coat of the small bowel and in the mesentery, varying in size from a pin's head to ¾ in. in diameter. About 12 in. of jejunum together with the larger mass of cysts was resected. Gastro-enterostomy. Uneventful recovery. Patient in fair health. On analysis, the gas in the cysts proved to be air. The wall of the cysts consists of a single layer of foreign body cells, with many lymphocytes and plasma cells.

**Idiopathic Gangrene of the Colon.**—B. J. FOWLER, F.R.C.S. (for H. BLACOW YATES, F.R.C.S.).

A 67-year-old housewife previously quite well was seized with severe persistent abdominal pain at 4 a.m. There was neither vomiting nor bowel action. The abdomen was flat, tender, rigid and silent. The pulse was regular. Laparotomy at 12 noon showed the colon to be gangrenous from the ileo-cæcal region to the lower pelvic colon. It was resected. Uneventful recovery followed. Later sigmoidoscopy showed no abnormality. Multiple sections of the vessels showed no thrombosis or embolism. Section of the colon showed necrosis mainly limited to the mucosa.

No member present had seen a similar case. A streptococcal causation was mooted.

**Localized Benign Ulceration of the Colon with Unusual Features.**—J. A. LLOYD DAVIES, M.B., B.S., F.R.C.S.

This ulcer (Fig. 1) was removed from the middle of the transverse colon of a diabetic woman aged 55 with a proctosigmoiditis of fifteen months' duration. For the last three months she has shown the clinical features of a severe ulcerative colitis. There were five additional similar discrete ulcers in the descending colon and one in the cæcum, but the remaining colon was normal. The histological changes are those of an ulcerative colitis, unlike the macroscopic appearances which show a sharp ulcer margin and normal surrounding mucosa. A focal arteritis is seen at the margin of the ulcer (Fig. 2), and an alternative diagnosis of necrotizing arteritis due to polyarteritis nodosa was suggested. Symptomatic recovery followed transverse colostomy and has been maintained for over a year, although some proctitis persists.

FIG. 1.—Benign ulcer of the transverse colon, with normal surrounding mucosa, from a patient with clinical features of a severe ulcerative colitis.

FIG. 2.—Section from the margin of the ulcer showing submucosal arteritis. →

[*December* 11, 1957]

## DISCUSSION ON NON-ARTICULAR RHEUMATISM

**Dr. B. G. B. Christie** (London):

No recognized classification of non-articular rheumatism has yet been established. In the past many of these conditions were described as "fibrositis", but more recent evidence reveals that this condition does not exist. The late Sir William Gowers (1904) labelled as "fibrositis" the changes which were thought to be present in fibrous tissue and which in their turn were the cause of the numerous aches and pains to which man is heir. The picture was clouded further by Stockman (1920), who described the changes of chronic inflammation in white fibrous tissue, a histological finding that has not been confirmed notwithstanding the innumerable biopsies that have been carried out.

Some of the pains previously ascribed to fibrositis tend to affect the mid-line posteriorly radiating out along the shoulder and pelvic girdles. Much of this pain arises from articular lesions in the spine itself, although in a small number of cases described by Copeman (1949) the pain has been shown to arise from herniated fat nodules. These may represent some of the fibrositic nodules or "trigger spots" that were commonly described in the past. The fibrositic nodule that may be felt beneath the skin, but which is so elusive at the time of biopsy, is probably a local muscle spasm, which may be a manifestation of referred pain.

### CLASSIFICATION

The only satisfactory classification of non-articular lesions must be on an anatomical basis, and the classification of Slocumb (1943) albeit of fibrositis is a useful beginning. This classification is:

(1) Intramuscular (myositis, "muscular rheumatism").
(2) Periarticular.
(3) Tendinous or fascial.
(4) Perineural.
(5) Bursal.
(6) Panniculitis.

To this I should like to add a seventh, namely

(7) Of bony origin.

(1) *Muscular Lesions*

Lesions in muscle are diagnosed because the muscle feels either doughy or hard to the touch and is tender on handling. Contraction of muscle will give rise to pain, and this may be elicited by active movement of the muscle and aggravated by resisted movement. Muscle pain is usually deep in character and defies accurate localization. Any lesion arising in muscles will then have these characteristics.

Patients frequently complain of pain following exposure to cold and dampness for which we still lack a satisfactory explanation.

Inflammation of muscle may be either (*a*) suppurative or (*b*) non-suppurative. (*a*) Suppurative lesions are rare and may be either primary or secondary to pyæmia and septicæmia. Primary myositis may be due to infection by staphylococci, streptococci or the organisms of gas gangrene associated with direct trauma. Secondary lesions are usually due to the chronic granulomata such as tuberculosis, actinomycosis and syphilis.

(*b*) Non-suppurative myositis is not uncommon and includes such conditions as fibrosing and ossifying myositis. In progressive myositis fibrosa the complaint is of stiffness more than pain, and the shortening of the muscles due to the fibrosis often gives a picture that resembles a symmetrical Volkmann's contracture of four limbs.

Myositis ossificans occurs in three clinical forms. *The first clinical type* is the classical ossification that takes place in the attachment of a muscle, such as that giving rise to the "rider's spur" at the insertion of the adductor muscles of the thigh.

*The second clinical type* is that occurring in the belly of a muscle usually as the result of direct trauma giving rise to a hæmorrhage, eventual calcification taking place. This type is called myositis ossificans circumscripta to differentiate it from the *third clinical*

*type*, progressive myositis ossificans, which differs from progressive myositis fibrosa only in the calcification that is seen in affected muscles. Pain is not so prominent in this group of conditions as tenderness and stiffness.

Tenderness of muscles is a feature of peripheral neuritis of whatever cause and is also associated with subacute combined degeneration of the cord. The neurological findings in these cases should direct attention to the primary lesion which usually overshadows the element of painful muscles.

Myositis is commonly seen in the so-called "collagen" diseases or with neoplasia especially carcinoma of the bronchus. In dermatomyositis the muscle element may precede or appear entirely separate from any dermatological involvement. When it does so the complaints are of vague aches and pains referable to muscles which themselves are weak and frequently tender to the touch. Palpation may reveal them to have the characteristic "doughy" consistency.

Recent studies in electrodiagnosis have shown that in many of these cases of dermatomyositis or polymyositis there is a characteristic picture, which may be of assistance in early diagnosis.

Intensity duration curves on the affected muscles often show varying evidence of denervation and when this is prominent the condition may be termed dermatoneuromyositis or polyneuromyositis. On electromyographic exploration spontaneous activity in the form of fibrillation or positive potentials will be seen when there is evidence of denervation on intensity duration curves. On volition there is a pattern which is compounded of potentials of less than one millivolt in amplitude, and less than one millisecond in duration. The affected motor units proclaim the dearth of active muscle fibres by the production of a crackly note on the loudspeaker and by assuming many of the appearances of a classical myopathy. The difference from the latter, however, is in the incomplete pattern, namely there is a qualitative decrease bearing a direct relationship to the degree of denervation present. A further characteristic finding is that samples from different points in the same muscle may produce a pattern that is both quantitatively and qualitatively normal.

About 10% of cases of polyarteritis nodosa are complicated by peripheral neuritis and it may be the presenting lesion. It is classically asymmetrical and in addition there is often pain in the limbs and muscle tenderness. Electrodiagnostically the findings associated with the peripheral neuritis do not segregate it from that due to other causes.

In scleroderma, or systemic sclerosis, the presenting symptom is frequently one of muscular pain leading the patient to diagnose his condition as "rheumatism". Further developments, such as tightness of the skin or dysphagia, usually eventually point to the correct diagnosis in this distressing condition.

Focal lesions of collagen occur in the muscles in systemic lupus erythematosus but the more florid manifestations of the disease will overshadow the muscular involvement. Many of these collagen diseases respond well to steroid therapy; in polymyositis and dermatomyositis marked clinical improvement has been paralleled by a return of the electrodiagnostic findings to normal after giving steroids in high dosage.

Myalgia has been reported in the scleroderma of Buschke (1900) but here again the œdema of the skin and its "hidebound" appearance are unlikely to make one think in terms of a primary muscle pathology.

Trichiniasis causes acute muscle pain when the infestation is severe and there is usually an associated eosinophilia. The muscles most commonly affected are the deltoid and gastrocnemius. It is important to differentiate trichiniasis, which causes acutely painful muscles five to seven days after infestation due to the migration of the larvæ of *Trichinella spiralis*, from cysticercosis of muscle which affects the same anatomical sites but is painless and only the cysticerci of *Tænia solium* are visible on X-ray due to their calcification.

Muscular aches and pains are frequently seen in endocrine disorders particularly acromegaly and myxœdema. In the former the facies and general appearance will probably disclose the diagnosis, but in myxœdema patients often complain of vague aches and pains related both to joints and muscles before their appearance is frankly myxœdematous.

In rheumatoid arthritis itself the involvement is widespread and frequently muscular aches and pains may be as troublesome to the sufferer as the joint lesions.

Muscle cramps occur in a large number of medical and especially neurological conditions. Special mention, however, should be made of muscle cramps that follow intervertebral disc lesions, especially those in the lumbar spine. These patients often suffer from night cramps in a leg that has previously been the seat of sciatica and it is interesting to note that the muscle group involved is frequently the one that was the site of the most severe pain at the time of the acute lesion. In my own experience I have found that the onset of these cramps frequently has a favourable prognosis in that it heralds the period of regression of the sciatic pain. Fortunately the cramps respond well to oral calcium lactate or to quinine.

(2) *Periarticular Lesions*

The main periarticular lesion to cause pain is capsulitis of the shoulder. Because there is capsular involvement there is of necessity limitation of movement in all directions. An interesting condition associated with capsulitis and occasionally missed is the shoulder-hand syndrome of Steinbrocker (1947). In this there is swelling and stiffness of the hand and forearm with skeletal rarefaction simulating Sudek's atrophy but without joint involvement. If the shoulder lesion is missed a mistaken diagnosis of rheumatoid arthritis in the hand is likely to ensue.

(3) *Tendon and Fascial Lesions*

In the third group are those conditions of tendinous or fascial origin. Tendinous lesions can only occur at those sites where well-developed tendons exist and these are mainly in the region of joints. Because of this proximity to the joints many pains arising from the tendons or their sheaths are incorrectly assumed to arise from the joint itself. The main site for tendon lesions in the lower limb is around the ankle-joint, and in the upper limb in the hand and wrist and to a lesser extent the shoulder. The commonest affection of tendons is a tenosynovitis, and the position of this inflammation is determined by anatomical considerations such as fibro-osseous tunnels or fibrous bridges, through or under which the tendons pass.

Tenosynovitis is of common occurrence in rheumatoid arthritis especially in the flexor tendons of the fingers. Because of its association with the joint disease the inability to flex the finger is often attributed to the arthritis of the interphalangeal joint. A simple test may be performed to differentiate these two. In the case of an arthritis of an interphalangeal joint flexion both active and passive is limited to the same extent and by pain. In tenosynovitis active flexion is limited and painful but passive flexion is full and painless because the tendon is not being called upon to move within its inflamed sheath. In many of these cases it is possible to palpate the thickened nodular tendon usually on the volar aspect of the metacarpal head.

There are four cardinal signs of tenosynovitis at any site:

(1) Pain on active movement of the tendon.
(2) Increased pain on resisted movements.
(3) Pain on passive stretching of the tendon in its sheath.
(4) Pain on palpation over the inflamed part of the tendon.

By applying these simple tests it is possible to determine the exact tendon sheath that is involved. This is now of great practical importance because of specific treatment with hydrocortisone. All the six tendon sheaths on the dorsum of the wrist must be examined individually in pain at this site to determine which one is affected, similarly one must examine the flexor pollicis longus, common flexor sheath and flexor carpi ulnaris in pain on the flexor aspect.

Textbooks frequently draw attention to the tenosynovitis of the common flexor sheath being tuberculous in origin. This is undoubtedly true, but such cases must be heavily outnumbered by those due to rheumatoid arthritis. Compound palmar ganglion occurring in the absence of other symptoms should arouse suspicion that it may be of tuberculous origin, although there may be no other overt evidence of tuberculous infection. When the swelling behind the flexor retinaculum is large further complications such as median nerve compression may arise.

Tenosynovitis around the ankle may arise in the extensor group anteriorly, the peronei laterally, or the tibialis posterior medially. This does not appear to be such a common site as the wrist, but in any pains arising in this region of the ankle that are non-articular in origin the tendon groups should be tested individually to exclude a tenosynovitis.

Two tendon lesions commonly occur in the region of the shoulder-joint affecting the long head of biceps and the supraspinatus tendon. In bicipital tendinitis the pain is situated in the deltipectoral groove on the front of the shoulder and brought on by elevation of the arm or movements of the elbow. To make a diagnosis one has to detect pain on palpation of the tendon in the bicipital groove and pain on flexion of the elbow and supination of the forearm. This pain is aggravated by the resisted movements.

The pain in supraspinatus tendinitis extends downwards from the point of the shoulder to the insertion of the deltoid and sometimes upwards to the supraspinous fossa and trapezius; more rarely it extends down the arm to the hand. Examination of the shoulder-joint reveals little or no limitation of internal or external rotation but a painful arc on abduction. The cardinal sign of a supraspinatus tendinitis in addition to the painful arc is pain on resisted abduction of the shoulder.

Tennis elbow is not strictly a tendinous lesion but one of the tenoperiosteal origin of the common extensor muscles from the external epicondyle and supracondylar ridge of the

humerus. The triad of signs characteristic of this lesion are pain over the external epicondyle on palpation, pain on gripping, and pain at the extensor origin on resisted extension of the wrist. In this respect it has the characteristics of a tendon lesion. Reverse tennis elbow or golfer's elbow has similar signs confined to the medial epicondyle and flexor origin.

(4) *Perineural Lesions*

The fourth category of Slocumb's classification is perineural and into this fall all pains of nerve origin.

Recent developments in electrodiagnosis have permitted the conduction times in peripheral nerves to be recorded and the speed of conduction determined. Simpson (1956) has shown that in cases of median nerve compression in the carpal tunnel there is a delay in conduction in the nerve as it passes the obstruction. This enables objective evidence in favour of nerve compression to be produced when the clinical picture of paræsthesiæ with absence of objective sensory or motor loss may be equivocal, and other electrodiagnostic signs negative. In more established cases the thenar muscles, especially the abductor pollicis brevis, show wasting and at this time there will be electrodiagnostic evidence of denervation, namely, change in the intensity duration curves and on electromyography spontaneous fibrillation with a reduced interference pattern on volition.

Pain in the hand is occasionally due to lesions of the ulnar nerve either at the wrist or the elbow. A ganglion arising from the joints of the carpus can cause aching in the hand which sooner or later gives rise to wasting of ulnar distribution.

The root pains from disc lesions sometimes have a less well-recognized pattern, and hence aching down the vertebral border of the scapula, deep in the muscles of the forearm, or in the palm extending to the middle finger may be due to a prolapsed cervical intervertebral disc with pressure on the seventh cervical root. In the absence of pain in the neck this may be misinterpreted unless the neck is examined when limitation of movement or with reproduction of the pain on movement will be observed. Similarly in the lower limb sciatic pain due to a disc lesion does occasionally present as a pain in the thigh, calf or ankle without a complaint of backache. Examination of the lumbar spine, however, in these cases reveals limitation of movement, and there is usually also limitation of straight leg raising.

Root pains due to primary or secondary neoplastic involvement do not differ in their distribution from those due to more benign causes, but their intensity, continuity, and failure to respond to treatment frequently differentiate them.

(5) *Bursal Lesions*

Lesions of bursæ may be painful and they have the common diagnostic feature of giving rise to pain when compressed. There are innumerable bursæ described by the anatomists any of which may be the seat of pain, and the following three are good examples.

At the shoulder the subdeltoid bursa covers the supraspinatus tendon and in the position of abduction is squeezed. As a result there is inability to abduct beyond a certain point. This is the case when the bursa is large or acutely inflamed. In the early stages there is a painful arc on abduction and again during the stage of resolution. The onset when acute is most dramatic, abduction both active and passive being exceedingly painful beyond a certain point. This serves to differentiate from a supraspinatus tendinitis in which passive abduction which does not require the tendon to move is usually painless. Similarly there is no increased pain on resisted abduction in subdeltoid bursitis. In neither of these conditions is there any appreciable limitation of external or internal rotation of the shoulder. The subdeltoid bursa may show calcification in its walls.

Sometimes a patient presents with pain in the buttock and walks with a limp—the picture suggests a lesion of the hip or sciatica due to a prolapsed lumbar intervertebral disc. Examination fails to confirm either of these diagnoses. The pain is in the buttock, usually behind the greater trochanter, and is aggravated by three movements: full passive flexion, adduction and internal rotation of the hip-joint. There is tenderness on palpation behind the trochanter. This is the clinical picture of gluteal bursitis and this bursa may also show calcification in its walls.

The tendo achillis bursa is situated between the tendon and the posterior aspect of the tibia. When inflamed it is painful on pinching between the finger and thumb and on forced passive plantar flexion. Active plantar flexion, however, namely standing on the toes, is painless, pain on this movement being due to a lesion of the tendon itself. There is usually some palpable thickening in the post-malleolar fossa.

(6) *Panniculitis*

The panniculitis syndrome has been well described by Baker (1951), and consists of painful subcutaneous fatty deposits especially on the inner aspects of the knees, thighs and arms, and is more common in women. Because the skin does not move appreciably on more-

ment of a limb this condition does not cause pain on movement but is painful on pressure or to the touch.

(7) *Bone Lesions*

Bones themselves may be a source of pain and this pain is frequently boring in type and present both on rest and on movement. Infections such as osteomyelitis, or neoplasms such as bone tumours or myeloma have characteristic radiological appearances. Of the tissues discussed so far the bones are the first that can always be seen on X-ray and which may present the diagnosis immediately. One is accustomed to seeing Paget's disease and the skeletal rarefaction associated with osteoporosis and osteomalacia, or more rarely the cystic changes of osteitis fibrosa cystica.

## Treatment

The advent in recent years of the steroid drugs in a form suitable for local injection has found its greatest application in the soft tissue lesions of non-articular rheumatism. They have brought with them, however, the need for greater accuracy in anatomical diagnosis if they are to produce their best results. It is useless to inject the second dorsal sheath at the wrist for a tenosynovitis of the first sheath. In the past many of these conditions were treated either by heat in some form, which was applied over a relatively large field, or by massage or frictions to the tender area. These methods are still used and are effective, but probably more effective is the injection of steroid provided that it is accurately placed.

The first of the steroids available for local injection was hydrocortisone acetate prepared as a suspension, this has now been widely used for three or four years and none of the newer chemical analogues has yet been proven superior. It was thought that by esterification and the production of hydrocortisone tertiary butyl acetate the action would be prolonged but in practice there is no convincing evidence that this is so. With the advent of prednisone (delta 1: cortisone) and prednisolone (delta 1: hydrocortisone) we have had an opportunity to experiment with prednisolone trimethyl actetate. In a small number of cases in which it has been used personally on soft tissue lesions it has failed to prove its superiority over hydrocortisone acetate. In non-articular lesions duration of effect does not appear as important as in articular lesions, as in the former one injection frequently cures and the assessment of comparative duration is impossible.

## Summary

Many non-articular lesions giving rise to pain were in the past loosely classed as "fibrositis", a concept which is now believed to be incorrect. This paper stresses the accurate diagnosis of non-articular lesions based on anatomical localization in conjunction with the characteristic symptoms and signs of the individual structures involved. This diagnostic accuracy is of increasing importance following the advent of steroid drugs in a form suitable for local injection.

*Non-articular Lesions in Rheumatoid Arthritis*

In rheumatoid arthritis non-articular lesions are important, for they occur frequently, they may give rise to severe pain and disability, and they are on the whole amenable to treatment. In the past these lesions seem to have been largely unnoticed or disregarded, and even now little reference is made to them in the current textbooks. In my survey of these non-articular lesions in rheumatoid arthritis I will discuss, firstly, the foot and ankle, secondly the hand and wrist, and lastly the neck and trunk.

## Foot and Ankle

*Metatarsalgia*

Patients with rheumatoid arthritis commonly suffer from severe pain in the forefoot which is extra-articular in origin. This pain arises in the region of the metatarsal heads and sometimes radiates along the sides of the adjoining toes. In such cases a localized area of exquisite tenderness can be found on the plantar aspect when pressure is exerted

between the metatarsal heads. Most often it is the space between the second and third metatarsal heads which gives rise to pain, but other spaces may be involved either singly or in combination. Though involvement of the metatarsophalangeal joints is common in rheumatoid arthritis, I believe that the lesion I have just described is secondarily rather than primarily due to the arthritis. My reason for this belief is that its response to treatment is similar to that of metatarsalgia in non-arthritic subjects.

Some benefit may follow the application of a metatarsal bar or a well-designed insole. The treatment of choice, however, is the injection of the tender area with an anæsthetic agent. The injection should be made from the dorsal surface of the foot just proximal to the metatarsal heads, the needle being pushed between the heads until the tender area is reached on the plantar aspect. In my experience an injection of procaine produces almost immediate and lasting relief of pain, and though it is now fashionable to use hydrocortisone as well, I doubt whether the results are any better than, or even as good as, when a local anæsthetic alone is used.

*Foot Strain*

Another common finding in rheumatoid arthritis is pain arising from the proximal and middle parts of the foot. This is due to foot strain, a condition characterized by pain and sometimes swelling in the mid-part of the foot which is intensified by movements of the mid-tarsal and subtaloid joints and which is sooner or later accompanied by limitation of movement of these joints. Unlike other types of pain in the foot this pain is often not relieved by rest and may actually be aggravated by it. Foot strain is an important factor in certain types of painful feet and is likely to occur when there is any interference with normal foot mobility. A supple foot, according to Wiles (1955) "whatever the habitual posture, seldom causes serious trouble, but a stiff foot, whether it is stiff because of an unresolved sprain, arthritis or contraction of the ligaments, is liable to become painful when subjected to strain".

In the milder cases contrast baths and foot exercises may produce improvement. In cases of any severity, however, the only reliable treatment is manipulation of the foot. This can sometimes be carried out without an anæsthetic; often, however, an anæsthetic is necessary as considerable force may have to be used by the manipulator. Many would hesitate to manipulate the foot of a patient with rheumatoid arthritis, but I am convinced that such caution is unjustified provided there is no osteoporosis.

I do not regard foot strain in patients with rheumatoid arthritis as a manifestation of the arthritis itself. Its pathology is the same as that of the foot strain which follows trauma or over-use, and of that which is liable to occur after a debilitating illness. The satisfactory response of foot strain in rheumatoid arthritis to manipulation again suggests that we are not dealing with a primarily rheumatic condition.

*The Painful Heel*

The association between pain on the under aspect of the heel and arthritis elsewhere has been known for many years, and was at one time believed to be diagnostic of a gonococcal infection. We now know this to be untrue just as we have now changed most of our views concerning gonococcal arthritis. The present situation is summed up by Short *et al.* (1957) as follows: "Experience gathered chiefly in World War II has clearly established that chronic progressive arthritis, resembling rheumatoid arthritis in clinical features and course, may be precipitated or aggravated by gonorrhœal infection but in no sense represents a form of chronic joint disease due to the gonococcus."

Kahlmeter (1933) seems to have been the first to realize not only that the painful heel was common in all forms of arthritis but also that it frequently preceded the onset of arthritis. Indeed he recommended that any patient with a painful heel should have an erythrocyte sedimentation rate and other blood investigations carried out as a routine. Since Kahlmeter other observers, among them Bywaters (1954), have noted painful heels to occur in rheumatoid arthritis. More recently it has come to be recognized that a painful heel may also accompany ankylosing spondylitis, and may indeed precede symptoms in the back. Such an association was first reported by Davis and Blair (1950). Therefore in all young men with heel symptoms the sacro-iliac joints should be radiographed and the E.S.R. estimated.

Kahlmeter believed that radiotherapy was the treatment of choice of this condition and most workers would agree that the painful heels of spondylitics clear up with this treatment. Good results are also often obtained with injection of hydrocortisone into the tender spot. Accessory methods of treatment include the wearing of a sponge rubber insole.

*Achilles Tendinitis and Sub-achilles Bursitis*

Lesions in the back of the heel occur in both rheumatoid arthritis and ankylosing spondylitis. Two structures may be affected: (1) the tendo achillis, and (2) the bursa

which lies between the tendon and the posterior surface of the calcaneus. Sub-achilles bursitis occurring in rheumatoid arthritis was described by Bywaters (1954) who found it to occur in 2% to 3% of patients. He found, moreover, that if the condition persisted erosion of the underlying bone occurred. Excellent illustrations of this phenomenon can be found in Bywaters' article. When pain is acute or much swelling is present the condition is easily recognizable. Often, however, symptoms and signs are not obvious and achilles tendinitis may easily be missed in a patient with rheumatoid arthritis with involvement of the ankle when it is assumed that it is the joint which is giving rise to all symptoms in this region. I have seen at least 3 patients who must have had achilles tendinitis for years in whom the condition had been missed and whose symptoms immediately cleared up following treatment of the tendon.

As with the majority of tendon lesions elsewhere, the introduction of hydrocortisone treatment by injection has greatly altered the progress and prognosis in this type of lesion. This is an additional reason why all patients with pain in the region of the ankle should be carefully re-examined in case a tendon lesion has been missed.

## Hand and Wrist

### *Tendon Lesions in the Hand*

The occurrence of tendon lesions in arthritis was described as long ago as 1827 by Scudamore, and Stockman (1904) used the term "rheumatic tendinitis". No further reference to such a combination seems to have been made until 1924, when Helweg of Copenhagen noted the frequency with which trigger fingers occurred in rheumatoid arthritis. Helweg's papers were followed by two others also by Scandinavian physicians, namely, Kahlmeter in 1933 and Edström in 1945. In this country the first full account of the clinical and pathological findings was given by Kellgren and Ball (1950), and more recently Brewerton (1957) has discussed the condition in some detail. Study of these papers makes it clear that tendon lesions will be found in a large proportion of cases if careful examination of the hands is carried out. So far as involvement of the flexor tendons is concerned there is notable consistency in the figures of Edström, Kellgren and Brewerton, the incidence being in the region of 35%. As regards extensor tendon involvement Brewerton's figures are considerably higher than those of the other two authors. If we sum up the findings of both flexor and extensor tendon involvement reported by these authors, Kellgren found them in 37 out of 100 patients; Edström in 163 out of 391 (41·7%), and Brewerton in 193 out of 300 (64%).

The more important lesions are those in the flexor tendons; they occur commonly in the tendons of the flexor sublimis either just above or below the metacarpophalangeal joints. Kellgren and Ball described three transverse bands which cross the tendons: (1) over the middle of the metacarpal bone, (2) over the metacarpophalangeal joint, and (3) over the middle part of the proximal phalanx. They found tendinous swellings to be present in the gaps between the bands. If these swellings were large the tendon was unable to move in the sheath and flexion was interfered with. When, however, the tendon involvement was less extensive, triggering of the finger was the presenting symptom. Brewerton found triggering in 101 cases and loss of active finger flexion in 28 cases. Both Kellgren and Brewerton state that the duration of symptoms from tendon lesions is usually not more than six months though it may be as long as thirty years (Brewerton). Kellgren points out that relief of symptoms may follow stretching or breaking down as a result of the inflammatory process of the fibrous bands to which I have just referred. It is perhaps the tendency for symptoms due to tendon lesions to clear up spontaneously that accounts for their being disregarded in the literature. I suspect, however, that lack of observation is a more correct reason.

Kahlmeter obtained excellent results from radiotherapy. Satisfactory results have also been reported to follow surgery. The whole situation as regards treatment has, however, been completely changed since the introduction of hydrocortisone which in a great majority of cases produces rapid and long-lasting relief. It is for this reason that tendon lesions should always be sought, even in the presence of underlying joint disease which may become relatively asymptomatic if the tendon lesion is treated.

### *Carpal Tunnel Syndrome*

The carpal tunnel syndrome needs only brief reference. Its characteristic symptoms of pain and "pins and needles", which wake the patient up at night, are found from time to time in cases of rheumatoid arthritis. It is my experience that these symptoms are readily controlled with a light cock-up splint worn at night. It is only very seldom that hydrocortisone need be injected, and I have not yet seen a case which required surgery.

### Neck and Trunk

Many patients with rheumatoid arthritis complain of pain in the neck and trunk which in the majority of cases is non-articular in origin. Pain is usually aching in character and is likely to develop when the patient is tired or undergoing stress. Some of the pain may arise from lesions in muscles which have been described by Gibson *et al.* (1946) and by several other authors. A more important cause, however, and one which may respond to treatment, is faulty posture, or as it is now sometimes called defective postural homœostasis. The term "postural homœostasis" was first used by Barlow (1952) who rightly disliked the use of the word "posture" by itself as it implied something static whereas in fact man is constantly changing his position not only during movement but also in response to mental stimuli. Barlow's thesis is an attractive one and it is also in keeping with modern biological thought which regards man and mammal as homœostatic machines (Young, 1957).

Pain of postural origin is the result of muscular over-use or of ordinary use in muscles unequipped to withstand the stress and strain of normal existence. Sometimes in addition, there is a second type of pain which is more constant and more severe. This arises from the insertion of muscles into bone and is particularly common at the insertion of the neck muscles into the occiput. A lesion in this situation may give rise to pain which is referred to the head, and results in a constant headache which may monopolize the patient's life. A lesion here is probably analogous to that of a tennis elbow; that is to say, it is situated at the insertion of muscle into bone, it is produced as a result of prolonged contraction or tension, and is aggravated by movements which contract the muscle.

Treatment of these cases is by re-education, a necessary requirement for successful therapy being an up-to-date knowledge on the part of the therapist of the physiology of posture and, in particular, of the role of the muscle spindle. In this last connexion the work of Hunt and Kuffler (1951) is of great importance since it suggests "that the muscle spindle mechanism, which mediates much of our postural sense, is put out of action by excessive muscular contraction" (Barlow, 1956). Thus in postural re-education the present-day emphasis on muscular relaxation is physiologically right, and the traditional method of concentrating on muscle strengthening and static holding exercises is physiologically wrong.

As a substitute for postural re-education any other form of physiotherapy is not justified. As an adjunct, however, particularly in the early stages, physiotherapy is sometimes of use. Heat, massage and certain manipulations, particularly traction, all may have a place as ancillary forms of treatment.

### Summary

(1) Non-articular lesions commonly occur in rheumatoid arthritis. They may give rise to pain and disability, and materially increase the discomfort of the patient. Examples of these lesions include: metatarsalgia, foot strain, the painful heel, achilles tendinitis and sub-achilles bursitis, tendinitis of the fingers and wrists, and the carpal tunnel syndrome.

(2) Most of these lesions respond satisfactorily to treatment, the prognosis having improved greatly since the introduction of hydrocortisone by injection.

(3) Pain in the neck and trunk occurring in subjects with rheumatoid arthritis is frequently non-articular in origin; it is often the consequence of faulty posture, in which case improvement follows postural re-education.

(4) Since the non-articular lesions of rheumatoid arthritis respond well to treatment they should be sought carefully in all patients with this malady and treated, no matter how severe the joint involvement.

## SYMPOSIUM ON WEATHER AND DISEASE

**Mr. R. G. Veryard** (Meteorological Office, Harrow):

*Availability and Processing of Meteorological Data*

There can be no disputing the fact that there is some kind of interrelationship, either direct or indirect, between many diseases to which man is susceptible and his geophysical and geochemical environment. The London "smog" disaster of December 1952 is a sad example. Yet in spite of the advances which have been made in medical and meteorological knowledge precise information is still lacking.

Now we all know that a little knowledge can be a dangerous thing, and this is particularly true of the science of Meteorology. I should therefore like to urge very strongly that the study of the relationship between weather and disease should be a joint effort on the part of experts in the various disciplines, meteorology, biology, physiology, &c.; the experts should work together as a team rather than as individuals. As an example, I can point to the joint efforts of the meteorologists and plant pathologists in the study of plant disease—efforts which have resulted in the issue, with a high degree of accuracy, of warnings of the outbreak of potato blight.

For the study of the relationship between weather and disease what meteorological data are available and how best can these data be used? First, I should mention that in this country, as in most other countries, meteorological observations are made mainly to meet forecasting requirements. By international agreement, surface observations are made at standard hours, 0, 3, 6, 9, &c. G.M.T. from a network of stations about 75–100 miles apart and upper air observations at the standard hours, 3, 9, 15 and 21 G.M.T. from a more open network of stations, about 150–200 miles apart. At many official stations, especially at airfields, additional surface observations are made every hour. To facilitate the processing of data by machine methods special forms have been devised for tabulating observations so that the information can be punched directly from the forms on to Hollerith cards. Now it is important for climatological purposes that observations be obtained from a much closer network than is needed for forecasting purposes—from a network that will include stations representative of the climatic characteristics of all types of terrain. To achieve this, the Meteorological Office has recruited about 500 co-operating stations—stations maintained by local authorities, research institutions, schools, colleges, and quite a few by private individuals. Most of these stations make observations once a day, at 9 G.M.T., and send in returns to the Meteorological Office at the end of each month. Then there are stations which provide autographic records—records of rainfall, of wind, of sunshine—as well as of temperature and pressure. Finally, there are a small number of stations which make observations of solar radiation—the direct beam, the diffuse radiation on a horizontal surface and the total radiation on a horizontal surface. A few stations record illumination and at Kew Observatory the net flux of radiation is observed. No routine observations are made of ultraviolet or of infra-red radiation: from the medical point of view this may be a pity as the ultraviolet in particular, and maybe the infra-red also, are believed to have an important bearing on human health.

In the archives of the Meteorological Office there is now a wealth of data available for research purposes. But it must be remembered that for many investigations, e.g. for the study of insect life, standard meteorological observations are of little use and it is necessary to make special observations with special instruments; the Meteorological Office has already carried out many micro-meteorological studies and can thus give useful advice regarding instrumentation for such work. It should also be borne in mind that it is misleading to think of climate in terms of averages. When considering questions of health and fitness, especially in a country which experiences such variable weather conditions as ours, extremes are important—especially extremes of radiation, temperature and humidity; but probably the greatest factor of all is the frequency and degree of the changes from day to day. There seems to be little doubt that most people react to changes of weather but it is still not known why, other things being equal, we should feel better in some weather conditions than in others. Maybe it is the cooling power of the atmosphere, maybe it is the ozone content, maybe it is the electrical state acting through the nervous system, or through

changes in the blood stream; but to determine what the factors really are careful scientific research is necessary.

Broadly speaking, there are three ways of carrying out bioclimatological and biometeorological studies—but it may be necessary to combine one method with another, or to use all three methods. The first is the purely statistical approach—the method of correlation, either to test some preconceived physical relationship, or to obtain some clue to a physical relationship. There has been an enormous amount of statistical work in the field of bioclimatology and biometeorology and, if I may say so, a large amount of this work has been quite fruitless—either because of misuse of statistics or misuse of data. For example, there is the misuse of long period meteorological records either because the data are not strictly homogeneous on account of changes in the "exposure" of the observing station (e.g. urbanization at Kew) or of climatic fluctuations, or because of the effect of "persistence". Moreover, meteorological factors do not operate as simple variables; each of several factors may influence animal response in a multi-variable manner.

A second method of investigation, which is common in meteorological and other physical sciences, is the dynamical or "energy balance" approach. A good example of this method, as applied to the field of biology, is a recent paper by Mr. C. H. B. Priestley, a meteorologist (1957). He shows how the heat balance of a sheep or other animal may be studied within the framework of a simple equation (to which Mr. E. N. Lawrence will refer later). The analysis carried out by Priestley largely separates the external or physical heat factors from the internal or physiological heat factors and thus facilitates the collation of experimental results and eases the burden on the field investigator.

This leads to the third line of attack on bioclimatological problems—the experimental approach, either in the laboratory or in "the field". A very good example of this is the work being carried out by physiologists attached to expeditions now in Antarctica who are studying the degree of acclimatization which man can acquire when he moves into a Polar region. The latter investigation has been described by Dr. Otto Edholm (1957).

One of the most neglected chapters in British climatology is the study of the health values of our climate. Fig. 1 (reproduced by kind permission of English Universities Press Ltd.,

FIG. 1.—"Bracing" and "Relaxing" climates.

from "The English Climate" by Dr. C. E. P. Brooks, 1954) shows what are called the "bracing" and "relaxing" areas of England and Wales and is based on the assessments obtained by a medical expert, Dr. E. Hawkins (1923). Maybe a meteorologist would have produced a similar map based on cooling power—I don't know. Anyway, I am sure a medico and a meteorologist working together would have produced a more reliable map!

**Mr. E. N. Lawrence** (Meteorological Office, Harrow):

*The Application of Meteorological Data to Medical Problems*

The problems here discussed arose mainly from enquiries received by the Climatological Services Division of the Meteorological Office. They are dealt with by meteorological or medical personnel or jointly.

Mr. Veryard has emphasized that "standard" meteorological observations cannot readily be used for micro-climatological study. Their limitations are well appreciated when trying to answer the common lay question "where to live?"—perhaps in connexion with some specific disease and stating interests or requirements such as low incidence of fog, low humidity or mild temperatures. This question can be answered broadly by describing regional climates, but the effects of local or micro-topography should not be ignored. A mere pimple of a hill, 100 feet high in an otherwise plain area, may experience significantly different minimum temperatures, wind regime and ground conditions. In an industrial area, an elevated site may receive considerably more sunshine; in hilly areas, sites sheltered from wind may experience more valley fogs, mist and frost. I have found a gradient of several degrees Fahrenheit per 100 feet of height in the temperatures at one to four feet above the ground around Elstree Hill—and similar gradients elsewhere in the country. To summarize, one should realize that micro-climatic or local differences can be just as important as regional differences.

Site selection concerns not only those seeking a healthy retreat but also local councils and the Ministry of Housing when planning satellite towns. Site selection and architectural and engineering design must allow for infrequent meteorological phenomena such as strong winds, tornadoes, tidal waves and floods, and the more general conditions upon which health depends, as, for example, the limits of wet and dry bulb temperatures, the requirements for treating certain diseases and, in some regions, the climates of insect-breeding areas (e.g. rain-made breeding pools for mosquitoes) and wind direction relative to insect habitats. Health depends also on sensory comfort, and psychological or æsthetic factors.

*Thermal* comfort conditions are illustrated by data from Kip and Courtice (1945) for the East Indies. The data show that slight air movement produces a marked shift of the comfort zone towards higher temperatures. Referring to *visual* comfort, one must distinguish between hot dry climates with glare from bright ground and sunlit buildings, and hot humid climates where discomfort is caused mainly by bright sky glare. *Olfactory* comfort and air pollution are closely related to wind direction and atmospheric stability. Regarding *acoustical* comfort, wind greatly influences noise dispersion. The speed of sound equals a constant times the square root of the absolute temperature plus the "following wind" component. Sound waves tend to be refracted downwards when wind increases with height and therefore also when temperature increases with height. Thus prevailing wind direction during temperature inversion may be considerably important in avoiding noise.

An interesting investigation by the Australian Meteorological Service, in connexion with the Olympic Games held at Melbourne during November and December 1956, compared the most likely weather conditions at Melbourne during those months with conditions at previous Olympic Games and conjectured whether athletic performance would be more or less favoured than hitherto. The full investigation is described in a paper called "Weather and the Olympic Games" (published by the Bureau of Meteorology of the Commonwealth of Australia) against the background of the heat balance equation:

$$M + S + H = E + R + C$$

where M stands for metabolism, S for storage, H for short-wave radiative gain and E, R and C the evaporative, long-wave radiative and convective losses.

In the equation, M, S, E and H may be measured and from this R + C may be calculated. The possible values of the heat balance terms are quoted in the paper. Unfortunately, the experimental work obtaining the results was enacted indoors under controlled conditions and with a very low rate of air movement, 0·2 mile an hour, and the factor representing air movement is open to doubt, as no work has been carried out (at least until recently) beyond an air speed of 6 m.p.h.

Below are some examples of work done by the British Climatological Services Division: Following the London smog disaster of December 1952 detailed information on air temperature, vapour pressure and the number of hours of "thick" and "dense" fog (over

a period of eight years) was supplied to the Statistical Unit of the Medical Research Council for use in investigations on atmospheric pollution.

Study of weather conditions during certain periods of noticeable damage to laundry supplemented chemical with meteorological evidence in an investigation to ascertain the source or sources of atmospheric pollution.

A further enquiry came from a research worker desiring to relate humidity to respiratory disease. The evaporation rate inside the respiratory apparatus may be estimated from the difference between inhaled and exhaled air. Let ingoing air have an absolute temperature T, a vapour pressure of e millibars and a volume V cubic metres per hour and exhaled air a temperature of 95° F. (308° A.), a relative humidity of 95%, and hence a vapour pressure of 53·5 millibars, and a volume of 308 V/T cubic metres per hour. The inhaled air will contain 216·7 e/T grams of water vapour per cubic metre or 216·7 eV/T grams per hour and the exhaled air will have $\frac{216{\cdot}7 \times 53{\cdot}5}{308} \times \frac{308\ V}{T}$ grams per hour and the difference between these values, i.e. 216·7 V (53·5-e)/T grams per hour represents the rate of loss of moisture. This expression indicates that the relevant "humidity" element is vapour pressure. In January, moisture loss is 25% greater than on an average day in July. On the coldest winter day, evaporation may be from 50 to 75% greater than on a sultry day in summer.

A further avenue of investigation concerns poliomyelitis. Briefly, much attention has been given to temperature and humidity (or some measure of atmospheric moisture content). The writer has computed (Lawrence, 1956) the correlations of maximum weekly notifications and total annual notifications with annual "accumulated degree-weeks" (computed from the weekly mean temperature in England and Wales) from a base of 60° F., and obtained values of 0·85 and 0·83 respectively, which are indeed rather striking. These results do not preclude a close relationship between poliomyelitis and some measure of evaporation or atmospheric "drying power", for the function of accumulated temperature employed is indicative of the atmospheric "drying power" of a particular summer in Britain.

**Dr. P. J. Lawther** (Medical Research Council Group for Research on Atmospheric Pollution, St. Bartholomew's Hospital, London):

*Climate, Air Pollution and Chronic Bronchitis*

The clinical condition of patients with chronic bronchitis may vary markedly from day to day. The influence of weather is commonly recognized and the serious effects of gross urban pollution have been manifest in various smog episodes. Recrudescence of infection is, of course, another important factor. In towns climate and air pollution are closely linked and both merit attention as possible ætiological factors in the production of chronic bronchitis as well as causes of exacerbation. It is important to recognize the separate nature of these divisions of the problem. Likewise it must be realized that the chemical and physical nature of polluted air is extremely complex and as yet ill-understood; pollution varies widely in both quality and quantity. Recent analytical work (Waller and Lawther, 1955, 1957) has shown that it is dangerous to regard smog as a specific miasma compounded of smoke and fog; it is wiser to regard fog and pollution as having more independent lives of their own, though obviously their coincidence is of chemical and clinical importance (Fig. 1).

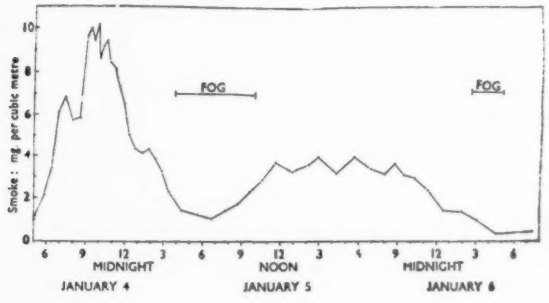

FIG. 1.—Concentration of smoke and occurrence of fog in London during a "smog" period in January 1956.

[From *Brit. med. J.* (1957) *ii*, 1473; by kind permission]

Smog is better referred to as acute urban pollution and it ought to be regarded as a rare and freakish occurrence. It is not merely a quantitative variant of the day-to-day airborne dirt. The effects of air pollution and various climatic factors may be investigated by two complementary techniques: the *experimental* approach involves the exposure of subjects to isolated factors under controlled conditions and the effects must be interpreted with due recognition of the limitations of the method. The *epidemiological* approach consists of the observation of the undisturbed patient in his carefully defined environment. Elaborate techniques are necessary only if the truth of the matter is deeply hidden, and the crude method described here illustrates the value of a simple initial approach to the problem of the separate effects of weather and pollution.

In 1954 patients who regularly attended a special clinic at St. Bartholomew's Hospital for chronic bronchitis and emphysema were given diaries in which they were asked to record their own assessment of their condition by means of a simple code

A. Condition **BETTER** than usual.
B. Condition **THE SAME** as usual.
C. Condition **WORSE** than usual.
D. Condition **MUCH WORSE** than usual.

The state of the group was plotted against pollution and climatic data and the value of this technique was quickly established when it was seen that an episode of acute pollution in the absence of fog resulted in marked clinical deterioration of the patients (Fig. 2).

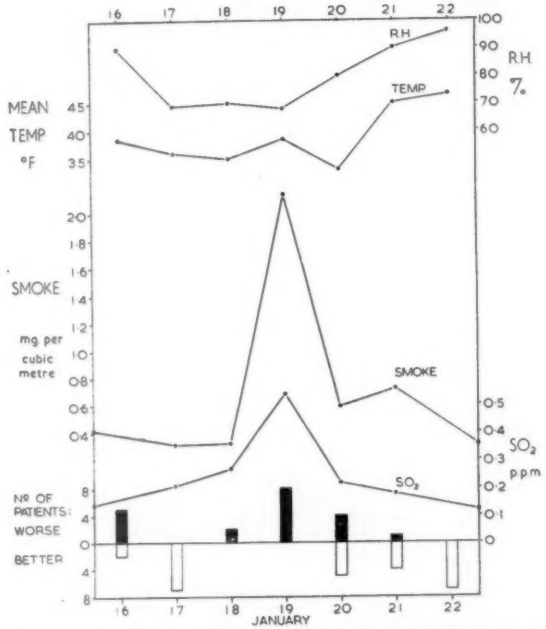

FIG. 2.—Graph showing effect on 29 bronchitic patients (St. Bartholomew's Hospital) of high pollution without fog.

[From *Brit. med. J.* (1955) *ii*, 1356; by kind permission]

A method of scoring was applied to subsequent results, from which was derived a figure called the "degree of illness":

$$A = -1;\ B = 0;\ C = 1;\ D = 2.$$

$$\text{hen Mean Score} = \frac{\text{Sum of scores for all patients}}{\text{Number of patients}}$$

he mean score provides a measure of the "degree of illness" of the group as a whole, inging from 0 to 1 in winter and falling below 0 in summer.

In the winter of 1955 the scheme was extended (with the kind help of Dr. C. M. Fletcher and other chest physicians) to five centres in London and others in the provinces. It was hoped that in the event of a smog disaster it would be possible to correlate the diary results with special tests made by the Department of Scientific and Industrial Research. These tests proved to be of limited value but the diary results yielded very valuable information. 180 diaries from patients in the London area were examined and the degree of illness of this population plotted against pollution and climatic data measured in central London (Fig. 3).

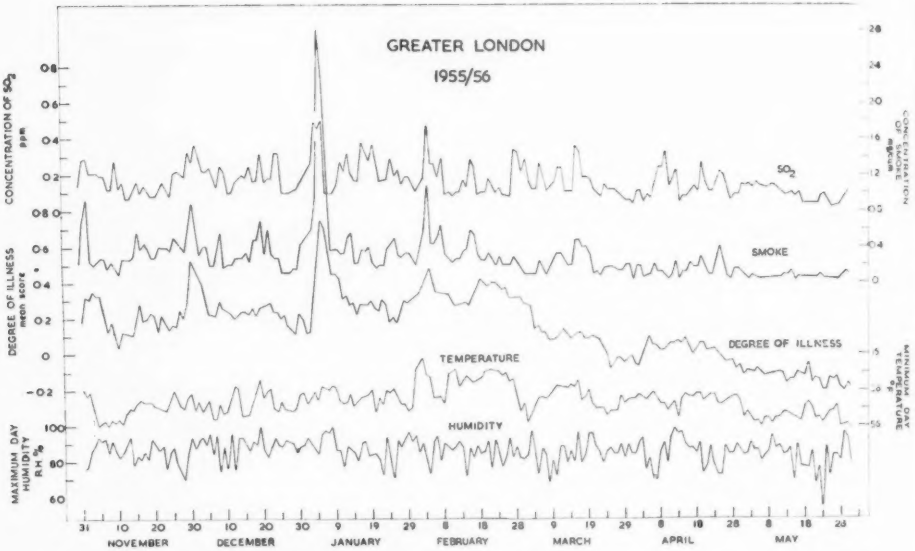

FIG. 3.—Graph showing degree of illness of a group of 180 patients in Greater London with chronic bronchitis, plotted with smoke and $SO_2$ concentrations, temperature and humidity.

[From *Instrument Practice*, 1957, **11**, 611; by kind permission

The degree of illness is seen to be more closely related to pollution than to any other factor during the winter months but this connexion disappears when pollution falls in the spring. It is noteworthy that decreases in visibility do not always correspond to a worsening of the condition of the group and this strengthens the suspicion that fog itself may play a less important part than was formerly thought. These results do not imply any direct causal relationship between smoke and $SO_2$ and the clinical state of the patients, but show that pollution, of which these substances are at least indicators, is probably causally involved. The scheme has again been extended and further analytical data, including sulphuric acid measurements, are being collected. The interpretation of these results is as yet very incomplete, but they provide for the first time evidence that chronic bronchitis is influenced markedly by day-to-day variations in urban atmospheric pollution.

**Dr. B. B. Waddy** (London School of Hygiene and Tropical Medicine):

*Atmospheric Humidity and Air-borne Epidemics*

The countries bordering on the south and east of the Sahara experience cerebrospinal meningitis (c.s.m.) in a way with which no other part of the world compares. For example, c.s.m. was epidemic in the United Kingdom in 1940 and 1941; adding together the figures for the two years the attack rate was roughly 1 : 10,000. Ordman (1932) gave an attack rate of 3 : 1,000 as the greatest he found in an exhaustive historical survey of the disease in southern Africa. In contrast to these figures, in a large area of Northern Nigeria the

*mortality* rate in a single season was estimated at 33 : 1,000, and in the cycle of epidemics in the western Northern Territories of Ghana with which I was concerned the total attack rate was 81·9 : 1,000. Lobar pneumonia also is an epidemic disease there.

Epidemics of this severity occur only during the dry season, and only in the dry savannah areas of the Sudan, Nigeria, Ghana and the intervening French territories. All epidemics end at the same time, the end of April. When c.s.m. is first introduced into a susceptible area the epidemic seldom gets under way until about the middle of February, half-way through the dry season. The first epidemic, therefore, is usually not a very big one. There are never more than occasional sporadic cases during the rains, but in its second dry season in an area the epidemic may start at the very beginning of the dry season—the turn of the year. With seven or eight weeks longer in which to develop, the second season's epidemic in an area tends to be the enormous one, and apparently leaves local mass immunity.

In the Northern Territories of Ghana it has been possible to trace the complete epidemiological picture of c.s.m. since its first introduction there in 1906. Apart from being confined to the dry season, intense epidemics are also confined to only the western side of the Northern Territories. The only explanation of this lies in the different types of house in common use. In the epidemic-free areas the dwelling consists of thatched round-houses each with a door opening on to a central compound; in the epidemic area the houses have mud roofs; they may be enormous in size, with perhaps 300 rooms, and most of the rooms are reached by internal connexions from very few outside opening doors. Inside them, therefore, there is a complete absence of ventilation and impenetrable darkness.

Epidemic lobar pneumonia has the same distribution and seasonal timing. Smallpox is not so strictly dependent on climate, but in the savannah smallpox epidemics invariably die out at the end of the dry season. Everything in this epidemiological picture is extremely clear-cut although no bacteriological work has been done. Glover's conception of the epidemic following in the train of an increased carrier rate would fit the observed facts of African c.s.m., if the carrier rate is dependent on dryness of the atmosphere. Initially, the carrier rate rises slowly from a small nucleus of migrant carriers, so that epidemic conditions take some weeks to ensue. At the end of the dry season carrier rate and epidemic die away rapidly and simultaneously, leaving a number of chronic carriers. These make a more widespread infective nucleus at the start of the next dry season, when the epidemic develops earlier.

In temperate climates, since the time of Hippocrates it has been known that air-borne epidemics tend to occur in late winter and after cold snaps, the change of weather taking about a month to take effect. Unless the epidemiology differs radically from that in the tropics, there must be something in common between the English home in February and the inside of a particular type of African house during the dry season. There are two such factors.

The first is a lack of daylight. Miller and Schad (1944) found that the meningococcus survived and kept its virulence for at least a week if kept dry and cool and in complete darkness, and that survival was roughly inversely proportional to the intensity and shortness of wavelength of light to which it was exposed. Field observations fit in with this finding. The evidence of the different types of house in Ghana is very striking. In England and Wales in 1940–41 there were higher attack rates in counties in which coalmining was the predominant occupation. In New Zealand, Dixon (1943) found an association with refrigerator workers. The common factor is darkness or artificial light.

The other factor is low absolute humidity (A.H.). In the epidemic zone of Africa, relative humidity (R.H.) drops extremely low during the dry season, and A.H. follows an exactly parallel course. In temperate climates A.H. is almost independent of R.H. and entirely dependent on temperature, being at its lowest in February and highest in July and August (Figs. 1 and 2). C.s.m. incidence in 1940 and 1941 showed obvious peaks at the nadir of the A.H. curve. In fact, the A.H. on a cold foggy day in England and a dry hot day in Africa are very much the same, 2 to 4 grams per cubic metre.

In Ghana in 1948 between case incidence and the A.H. of four weeks previous there was a correlation coefficient of −0·53, s.e. 0·20. In this country, the only prolonged series of carrier rates of which I know is that of Glover (1918). The correlation coefficient between carrier rate and A.H. of four weeks previous was −0·78, s.e. 0·29. The A.H. figures were outdoor ones, but experiments I made myself during the winter of 1947 showed that the indoor A.H. does not rise very much above that outdoors (Waddy, 1952).

Elsewhere in the tropics, Rogers (1926) correlated smallpox and lobar pneumonia with low A.H. The association of the three waves of the 1918–19 influenza pandemic with cold dry weather was noted both in this country and in France. More recently Thorburn (1957) correlated air-borne infections with low A.H. in southern Africa.

There is experimental evidence that air-borne organisms do live longer in conditions of low A.H. (de Ome, 1944; and Loosli *et al.*, 1943). As far as is at present known, therefore,

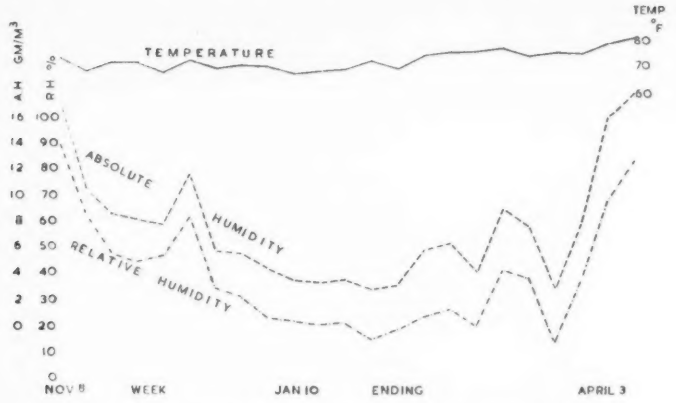

FIG. 1.—The tropical dry season. Ghana, 1947–48.

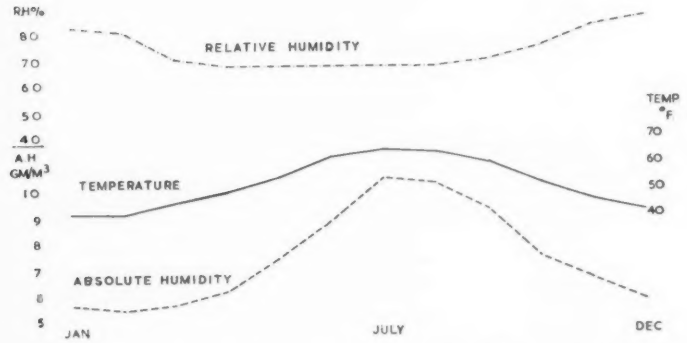

FIG. 2.—Average temperature, relative and absolute humidity in England (Harrogate).

bacteriological evidence supports field epidemiology. So does physiological evidence. The amount of water that has to be evaporated in the upper respiratory passages and added to the inspired air depends on the absolute, not relative humidity of the outside air. Looked at from this point of view, the saturated air of a February day, A.H. about 4 grams per cubic metre, is very much drier than that of a hot dry July day, A.H. about 11 grams per cubic metre. The evaporation of water produces also a cooling effect, and it is well known that ciliated epithelium does its job sluggishly when cooled. This may well apply specially when there has been a sudden change of weather, before physiological adaptation has taken place.

## DISCUSSION ON THE COMMON COLD

**Dr. R. E. Hope Simpson** (Cirencester):

When we have been baffled by a problem for a sufficient time, when we have assaulted it with this theory and that hypothesis and it remains unsolved to plague us both intellectually and physically, it may be that the time has come to imitate Joshua, to draw our forces a little way off, to march round and round our problem considering it from every angle. Inferences may then suddenly become so plain to us that we blow loudly on the trumpets of a new idea and down tumble the impregnable walls. Some such feeling has animated our approach to the problem of the common cold, a fortified city that has so far successfully resisted the most determined and persistent frontal attacks. I shall consider one aspect from my own vantage point.

For many years we studied the broad picture of respiratory disease as presented to us in general practice. In particular it seemed important not to assume that colds were infectious unless the facts proved them to be so and I shall quote certain features of the epidemiology of colds which are inexplicable by a theory of simple transmission.

J. J. van Loghem collected records from nearly 8,000 volunteers in various parts of Holland. He analysed them separately for seven different regions of Holland and found nearly the same incidence in each region, and that the secular curves of morbidity of each had approximately the same troughs and peaks. It is as if one started measles in seven different parts of a country simultaneously, then selected susceptible volunteers at random from the seven different regions, and when the epidemic was over one found that the measles amongst the volunteers gave identical curves of prevalence and incidence in each region. Such a thing would be an incredibly unlikely coincidence, yet this actually happened with colds and has since been confirmed by Frost and Gover and again by Tucher in the United States. Some other powerful agency must be in operation besides case-to-case transmission, if such indeed does occur.

Rarity and commonness in diseases are interesting characteristics worthy of close attention. A common disease presents the difficulty that its very abundance may make it almost impossible to decide whether case-to-case transmission occurs or not. Colds may be so abundant that the appearance of transmission is simulated by chance alone.

A second characteristic, in addition to the extreme abundance of colds, is their seasonal tide. The five-year average of cases of respiratory disease presenting in each calendar month in the practice gives a curve with its peak in the winter months and its nadir in the summer. The thirty-five-year average each month for the air temperature when inverted shows a broad parallelism with the respiratory disease curve.

This parallelism with the temperature did not hold for cases of sore throat. It seemed that a big group of respiratory illnesses, the commonest diseases with which we have to deal, followed a seasonal trend running to abundance in the cold weather, and that another symptomatically distinct respiratory group did not. This crude epidemiological observation merited a closer scrutiny. We therefore enrolled some 350 volunteers, about 80 families, who keep a daily record of certain respiratory symptoms.

*Incidence.*—We had two main objectives, firstly to discover in detail the true incidence, and secondly to see how closely colds paralleled the changes in seasonal temperature. Here again we tried to shed our preconceptions. We did not in the first place record colds, separate illnesses, as units or episodes but we recorded the daily morbidity in case colds were not episodes of illness like measles. We hoped that the facts if adequately and accurately elicited would speak for themselves. We did not know what other mode of illness there might be. Perhaps a state of chronic morbidity with the morbid process increasing in severity every now and then so that its toxicity rose above the threshold of symptom production and then again sank below it, or perhaps a latent virus infection prompted to periodic activity by extraneous agencies in the manner of herpes simplex virus, or again, perhaps the normal bacterial flora prompted to unwonted activity by the advent of viruses passing continuously from person to person. Whatever the possibilities we had no right, in view of the quite different epidemiological picture presented by colds, to carry over to this enquiry conceptions based on the epidemiology of diseases like measles and typhoid fever. If we can be sure of anything, we can be sure of this, that in colds we have to deal with a mode of illness totally different from those.

Each of us probably suffers from measles for two of the 3,500 weeks of his life. How long do we suffer from colds? Our figures for 1954 and 1955 suggest that we probably suffer from a cold for 700 weeks of our life—one-fifth of our days. During each of these years the average for man, woman and child was seven episodes of respiratory illness averaging ten days each—seventy days per annum.

Though this may be a minor disease it is not a minor mode of illness.

*Seasonal link.*—How closely are colds associated with cold?

The secular curve of morbidity from colds amongst our volunteers was compared continuously on a comparable scale with the inversion of the temperature taken a foot deep in the earth. This gives a good picture of the seasonal temperature damping out the effects of brief erratic changes in the air temperature (Fig. 1). The concordance between the two curves is remarkable. It seems that the temperature has only to drop 1° F. for the morbidity from colds to rise by about 1%.

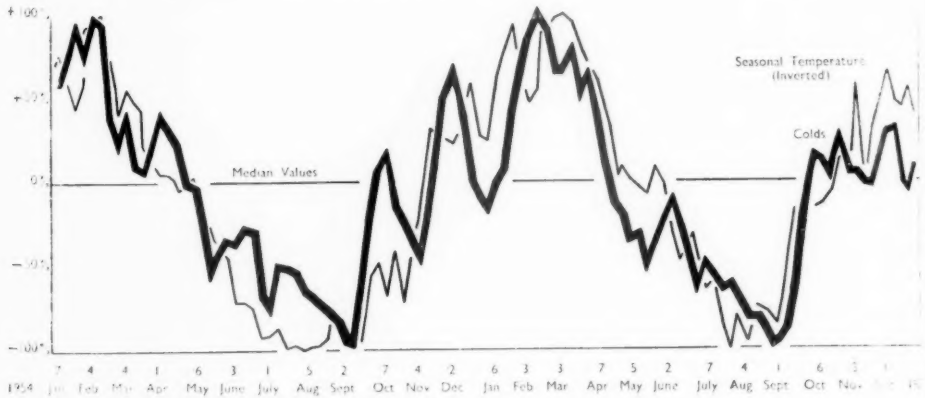

FIG. 1.—*Morbidity from colds with seasonal temperature* 1954 *and* 1955. Thick line—percentage of volunteers showing symptoms. Thin line—earth temperature (inverted).

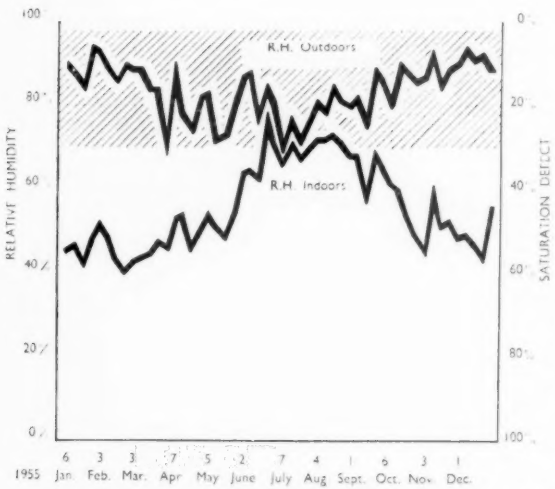

FIG. 2.—*Relative humidity outdoors and indoors* 1955. Top curve—relative humidity at 10.0 a.m. outdoors. Lower curve—relative humidity at 3.0 p.m. indoors. Shaded area shows the usual range of natural outdoor relative humidity.

It is, of course, possible that the drop in seasonal temperature itself directly causes the increased morbidity, but one finds difficulty in accepting this solution of the problem. The effect may be secondary, mediated through another agency acting directly on the human organism, an agency the effect of which varies in intensity with the seasonal temperature change. This seems the more likely because most of us spend much of our time, especially in winter, in temperatures far removed from those of the outside air, and yet it is in winter particularly that we must seek the baleful agency. In the search for this agency our suspicions were aroused by the humidity of the indoor atmosphere, or, to be more precise, by the converse of

the humidity, the evaporating power or dryness of the air. Here is an agency acting directly on the respiratory apparatus in the most intimate fashion imaginable.

Direct evaporimetry is tricky, but it is fairly easy to obtain a measure of the drying effect of the air from the saturation deficit and the temperature. The saturation deficit tells us in percentages how much more water vapour the atmosphere can accommodate, and the temperature allows us to envisage the avidity of the air for water. The usual range of humidity of the outdoor air in our part of the world is from 70% to 98% with an average of about 80%. This has a deficit of from 30% to 2%. For a brief period in summer the air indoors reaches this "natural" state of humidity (Fig. 2). For most of the year, however, the air indoors is considerably drier than the outdoor air.

The difference in humidity between the atmosphere indoors and outdoors gives a curve over the year that approximates very closely to that of the morbidity from colds, in fact we may say that the increase of colds and the increase of dryness due to artificial heating run closely parallel (Fig. 3).

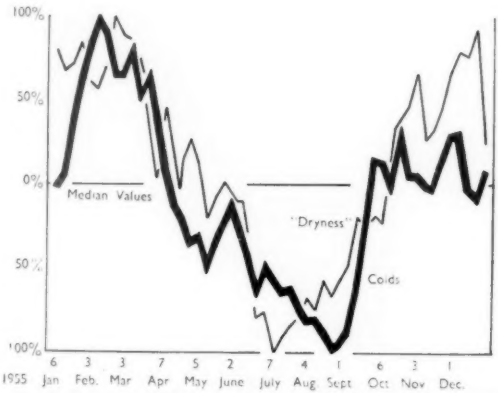

FIG. 3.—*Colds and indoor dryness* 1955. Thick line—morbidity from colds. Thin line—difference between relative humidity outdoors and indoors.

Our respiratory apparatus requires that the air shall be fully saturated with water vapour if it is not to suffer severe damage. Lassen discovered this tragically when poliomyelitis hit Denmark and produced the great crop of cases of bulbar palsy. They found themselves faced with numerous patients unable to breathe and only two iron lungs in the country. Lassen rapidly improvised methods of positive-pressure respiration with anæsthetic apparatus. He found that unless the gases were fully saturated the patients developed respiratory infections. Here is clear evidence of the importance of an adequate content of water-vapour, and we know that there is an apparatus in the human nose and upper respiratory passages for saturating incoming air. This humidifying apparatus, it is reasonable to suppose, is designed to meet the exigencies of the "natural" variations in humidity, but the conditions indoors depart widely from anything that we meet outdoors, especially in winter. Moreover, the effect is enhanced enormously by the temperature. For each 10° rise in temperature we get a

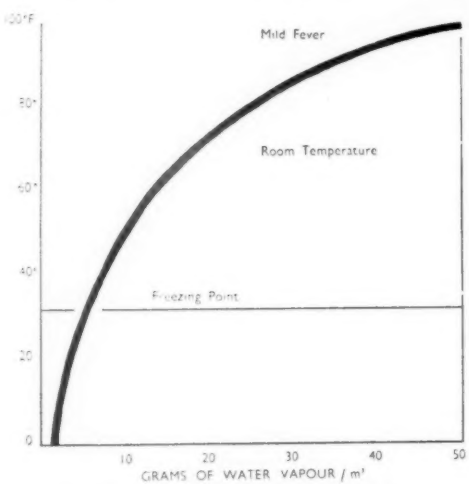

FIG. 4.—*The saturation content of the air at different temperatures.*

proportionately increasing capacity of the air to store water, coupled with an enhance molecular activity, so that the thirst of the air develops enormously as one proceeds u the scale (Fig. 4).

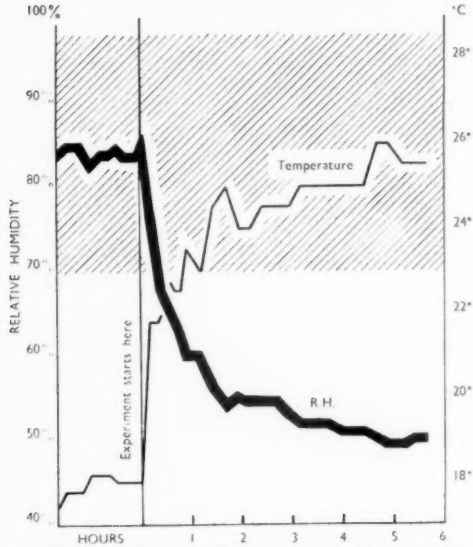

FIG. 5.—*Impotence of open door and window to keep the room moist after switching on a one-bar electric fire.* Thick line—relative humidity. Thin line—temperature. The relative humidity drops rapidly below the natural (shaded) level.

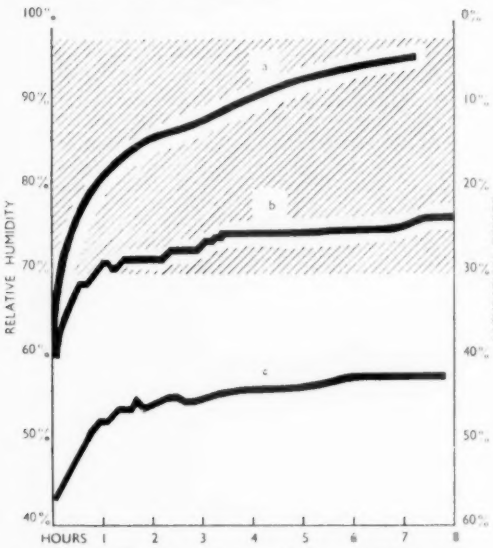

FIG. 7.—*The effect of a humidifier.* (*a*) Without any artificial heat (room temperature 20° C.). (*b*) With a single-bar electric fire (room temperature 25° C.). (*c*) With a double-bar electric fire (room temperature 30° C.). Shaded area represents "natural" relative humidity.

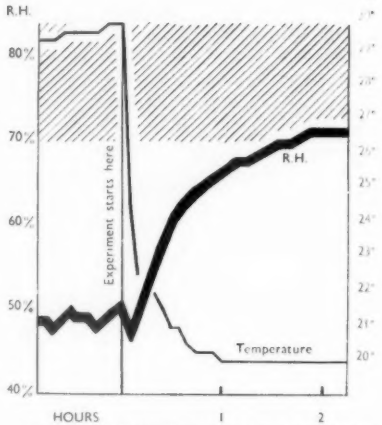

FIG. 6.—*Effect of opening door and window in a dry hot room without a source of artificial heat.* Thick line—relative humidity. Thin line—temperature. The humidity rapidly rises to a natural level (shaded area).

The bronchial tree is lined with ciliated epithelium continuously in action wafting a stream of mucus in spiral fashion towards the mouth. Upon this mucus stream fall all the particles of dust, the airborne bacteria, and viruses. They are washed upwards until they reach the mouth and are swallowed. Dry air can so thicken the mucus that it impedes the action of the underlying cilia. Over long periods of time this might lead to areas of irritation and damage to the underlying cells and certainly would impair the cleansing mechanism of the respiratory tract. Bacteria and viruses might find themselves in regions unaccustomed to their presence, locally non-immune, so that they might set up temporary inflammatory processes. Osmotic changes in the cells might also lead to trouble.

Opening the windows of the room does not put all this right. When the room is moist and cool to a degree equivalent to the outside air and the electric fire is switched on, the atmosphere rapidly becomes warm and dry and in almost no time the humidity is far below the outdoor level (Fig. 5). Switch off the fire and open the door and window and the air soon becomes moist (Fig. 6). Even with a humidifier

continuously working it is difficult to bring the air into the region of natural humidity whilst an electric fire is switched on (Fig. 7).

*Summary*.—The common cold is a mode of illness that attacks with a frequency far outstripping that of any other disease. The incidence is so closely correlated with seasonal temperature that a drop of 1° F. is associated with an increase of 1% in morbidity. We found that the drying and warming of the air by the artificial heating in our houses provided a most suggestive association with the morbidity from colds.

It is difficult to design an experiment to settle the importance of this factor, but we were fortunate enough to obtain a record which contributes to the subject. A cheese factory in Wales was recently provided with a room kept at a temperature of about 57° F. and a humidity of 80%. It was feared that the workers in this room might suffer from the high humidity and cold atmosphere. In fact over a period of twelve months their morbidity rate was less than half that of the other workers in the factory.

**Dr. A. T. Roden** (London):

*Clinical Assessment of the Common Cold*

While engaged in a study of the records of the Common Cold Research Unit at Harvard Hospital, Salisbury, I became interested in the question—What criteria does the clinical observer use in making his assessments?—and as a corollary to that—How consistently does he apply them?

The volunteers who come to this Unit live, usually in pairs, in isolation accommodation. Clinical observations are recorded daily. For my present purpose I have abstracted from the records the following signs and symptoms—nasal discharge, nasal obstruction, sore throat, cough and pyrexia.

Table I shows such an abstract from the record of an individual volunteer. The days

TABLE I.—MILD COLD

| | Days 1 | 2 | 3 | 4 ↓ 5 | 6 | 7 | 8 | 9 |
|---|---|---|---|---|---|---|---|---|
| Clear discharge .. | | | | | + | + | ± | ± |
| Purulent discharge | | | | | | + | ± | |
| Extra handkerchiefs | | | | | 9 | 30 | 15 | 1 |
| Nasal obstruction | | | | | | ± | ± | |
| Sore throat .. | | | | ± | ± | | | |
| Cough .. .. | | | | | | | | |
| Fever .. .. | | | | | | | | |

TABLE II.—MODERATE COLD

| | Days 1 | 2 | 3 | 4 ↓ 5 | 6 | 7 | 8 | 9 |
|---|---|---|---|---|---|---|---|---|
| Clear discharge .. | | | ± | | + | + | + | + |
| Purulent discharge | | | | | + | + | + | + |
| Extra handkerchiefs | 1 | 1 | | 1 | 8 | 11 | 7 | 6 |
| Nasal obstruction | | | | | | + | | ± |
| Sore throat .. | | | | | + | | | |
| Cough .. .. | | | | | | | | ± |
| Fever .. .. | | | | | | ± | | |

begin and end at noon. The first four days were a preliminary period of observation during which the volunteer was free from symptoms. At the end of the fourth day infective material—from the nasal secretions of a person suffering from a common cold—was administered by intranasal instillation. Within twenty-four hours—or to be more precise about eighteen hours—after administration the volunteer felt a slight soreness of the throat. The next day there was an increase of nasal discharge, at first clear but, by the following day, muco-purulent. At the height of the nasal discharge there was slight nasal obstruction. No cough. No pyrexia. The assessment—mild cold.

Here is an example of a minor respiratory illness of which the predominant clinical manifestation is an increase of nasal exudate. Now, in my reading of the medical literature, I have yet to come across any adequate description of the quantity of the nasal discharges either in health or in disease. I may not have carried my reading far enough. But if I am right this is a very surprising omission. Because a rough quantitative estimate can be based on quite simple observations and would, presumably, have been made by many clinicians if it were thought to have a diagnostic value.

The extra handkerchiefs used were of paper. They are called "extra" because each volunteer is allowed one as a normal daily ration. The symbol + against nasal discharge indicates that the quantity on the handkerchief was such that it could not be used again without unpleasantness. The symbol ± indicates a perceptible quantity but such that the handkerchief could have been used again.

Table II shows another individual record. Again there is the same preliminary period of observation during which there was a little insignificant nasal discharge. On the second day after administration of infective material—coryza and sore throat. At the height of the coryza, transient slight pyrexia—in this instance about 99·6° F. Later some slight cough. The assessment—moderate cold.

The assessment is interesting. The degree of coryza just exceeds the minimum amount

in category 4 of our arbitrary scale (*see* below) with 8 extra handkerchiefs on one da and 11 on the next. In Table I the volunteer with the mild cold used 9 extra handkerchief on one day and 30 on the next. So the severity of the cold has been judged not by th degree of coryza alone but by the combination with other symptoms and by the genera misery of the patient.

The following is a summary of observations on a total of 407 volunteers, of whom 19 were given positive control material—that is material from persons suffering from a col and, therefore, presumably infective—and 209 were given negative control material—tha is some inert fluid. I have not brought into this summary any volunteers given cultur materials under test for the presence of virus.

All the assessments were made by one clinical observer and all his observations o positive and negative control groups have been included. The volunteers were allocate at random to their groups and neither they nor the observer were aware of the nature of th material used until the assessments had been recorded. This is a normal experimenta precaution against bias.

In Tables III to VI the degree of coryza—using coryza as a synonym for increased nasa discharge—is represented on the following arbitrary scale:

0 = None or ± only.
1 = + on one day only.
2 = + on two days or more.
3 = + with at least 8 extra handkerchiefs on one day only.
4 = + with at least 8 extra handkerchiefs on two days or more.

Table III shows the correlation between the degree of coryza on the arbitrary scale and

TABLE III.—CORRELATION OF CORYZA WITH OTHER SYMPTOMS

| | | Other symptoms | | |
|---|---|---|---|---|
| | | − or ± | + | %+ |
| Degree of coryza | 0 | 263 | 17 | 6·1 |
| | 1 | 26 | 4 | 13·3 |
| | 2 | 25 | 20 | 44·4 |
| | 3 | 3 | 9 | 75·0 |
| | 4 | 3 | 37 | 92·5 |
| | Total | 320 | 87 | 21·4 |

the presence of one or more of the other symptoms and signs which I have mentioned. This correlation may be taken as evidence that both the coryza and the other symptoms have a common causation.

The figures from the second and third columns of Table III are set out thus: 263 in the category 0−, 17 in the category 0+ and so on, in relation to the clinical assessments.

Table IV shows our ten categories and the assessments—no cold (−), doubtful cold (±),

TABLE IV.—RELATION OF ASSESSMENTS TO SYMPTOMS

| | | Assessments | | | | | |
|---|---|---|---|---|---|---|---|
| | | − | ± | m | M | S | Total |
| Degrees of symptoms | 0− | 254 | 9 | — | — | — | 263 |
| | 0+ | 11 | 5 | 1 | — | — | 17 |
| | 1− | 20 | 5 | 1 | — | — | 26 |
| | 1+ | 1 | 3 | — | — | — | 4 |

| | 2+ | — | 7 | 9 | 4 | — | 20 |
| | 3− | — | — | 3 | — | — | 3 |
| | 3+ | — | — | 6 | 3 | — | 9 |
| | 4− | — | — | 3 | — | — | 3 |
| | 4+ | — | — | 13 | 19 | 5 | 37 |
| | Total | 294 | 39 | 43 | 26 | 5 | 407 |

mild (m), moderate (M) or severe (S) cold. It will be observed that in categories 0 and 1 only 2 out of a large number reach an assessment of mild cold. In categories 3 and 4 all are assessed as colds. Between, in category 2, there lies an ambiguous zone. In each category it will be seen that the presence of other symptoms influences the assessment.

Tables V and VI show the degree of coryza and the assessments in relation to the experimental procedure.

TABLE V.—NEGATIVE CONTROLS

| | | Assessments | | | No. of cases |
|---|---|---|---|---|---|
| | | − | ± | + | |
| Degree of coryza | 0 | 176 | 7 | — | 183 |
| | 1 | 10 | 2 | — | 12 |
| | 2 | 5 | 8 | 1 | 14 |
| | 3 | — | — | — | — |
| | 4 | — | — | — | — |
| | Total | 191 | 17 | 1 | 209 |

TABLE VI.—POSITIVE CONTROLS

| | | Assessments | | | No. of cases |
|---|---|---|---|---|---|
| | | − | ± | + | |
| Degree of coryza | 0 | 89 | 7 | 1 | 97 |
| | 1 | 11 | 6 | 1 | 18 |
| | 2 | 3 | 9 | 19 | 31 |
| | 3 | — | — | 12 | 12 |
| | 4 | — | — | 40 | 40 |
| | Total | 103 | 22 | 73 | 198 |

Table V—the negative control group—shows that in no instance did the degree of coryza rise above the ambiguous zone. One volunteer out of 209 managed to achieve assessment as a mild cold.

Table VI—the positive control group—shows the degree of coryza observed and the assessments made of definite colds in 73 out of 198 volunteers.

I have used these data to illustrate two aspects of the rationale of clinical judgments.

First by an examination of the primary observations to ascertain the degree of consistency of the assessments.

Second to test the validity of the clinical concept against some factor—in this instance the nature of the experimental procedure—which is independent of the clinician's judgment.

**Dr. J. Morrison Ritchie** (Birkenhead):

In 1930, when the Birkenhead Municipal Laboratory was opened, a female clerk of the M.O.H. Department who had been a martyr to colds for years was very persistent in demanding treatment. On the understanding that she would have an injection once a week during the following winter no matter what happened, I made her an autogenous vaccine from her sputum.

She went through the winter without a cold, the first time for years. At the end of the following summer (1931) she and several others asked for a vaccine. They all had a winter without colds, although some had the prodromal stages. We then had, for years, a procession of corporation staff, much against my will, but it soon seemed that our only failures were where actual damage had occurred to mucous membrane. The theory was evolved that the function of the virus might be essentially to depress resistance, so giving the normal (though heterogeneous) nasopharyngeal flora a more or less free hand—in other words, the virus is a kind of starting handle.

When the Birkenhead Laboratory was taken over by the Public Health Laboratory Service, permission was obtained from Professor Wilson for a controlled experiment, and a series on approximately 200 volunteers was carried out during the winter of 1955–6, in conjunction with the factory at Port Sunlight. Of these, allowing for wastage, 109 were given autogenous vaccines prepared from their saliva, while 75 got saline injections only. Apart from prodromal stages, i.e. a clear running nose for a couple of days (presumed to be the virus activity which was relatively unaffected), the percentage of full colds was six times as high in the controls as among the vaccinees who were able to carry on throughout the winter. I gave the vaccines, while assessment was carried out by Port Sunlight's staff, who did not know who were controls.

This was very encouraging, but naturally autogenous vaccines on a large scale are not practicable, so the idea was tried of tackling the problem from the opposite angle, i.e. instead of boosting the patient's resistance, to depress the activity of the bacteria at the appropriate time. Without going into details, the proposal was to do a series of sensitivity tests on the saliva of volunteers and card the results, this being done before the cold season began. Then, when each reported the beginning of a cold, the works Medical Centre

would issue the appropriate antibiotic tablets. In short, the idea now was to balance the depression of the patient's resistance by a corresponding temporary depression in the activity of the bacteria. The minimal dose of four tablets spread over two days was used to avoid interference with the patient's normal flora or the production of insensitive organisms.

For this later investigation, altogether just over 1,000 volunteers were available, in half a dozen works, a large office staff, and a school, all assessment being done by the Medical Centres concerned. Inert tablets were used as controls. The Birkenhead Police also co-operated, using the Laboratory as Medical Centre, and they became a day-to-day check on the investigation, without controls, being for this reason excluded from the investigation itself. This check was very useful, as it was found that in a few cases four tablets gave a rather short course and five or six would abort the condition. Once more the clear running stage for twenty-four to forty-eight hours was regarded as prodromal, due to the virus, but it was strange how many people used the phrase "turned off like a tap" after that period.

There were 22/581 colds among those receiving antibiotic tablets on the first day, as against 87/338 among those receiving inert control tablets—3·8% as against 25·7%, a drop to one-seventh. In the adult industrial population, the proportion was one to nine, and this drop was evident in all the units of the investigation.

## Application of the Findings

(1) *In industry.*—Where a works has a Medical Centre, the antibiotic method is simple and consists of: (*a*) Preliminary sensitivity tests by a laboratory, results being carded and filed in the Medical Centre. (*b*) Substitution of the appropriate antibiotic tablets for whatever palliative has been used in the individual works concerned. (*c*) Taking care not to overdo the antibiotic, and that the approval of the patient's own doctor is obtained.

(2) *In practice.*—A. The antibiotic method is less easy to carry out because:

(*a*) Patients are not likely to report at a surgery on the first day, and, while the antibiotics will work even if given later, the whole idea is to forestall the attack by the patient's flora, and where that has begun the treatment is naturally at a disadvantage.

(*b*) Antibiotics should not be issued casually, nor should they be freely available to all and sundry.

An interesting point is that a number of practitioners have been treating some early influenzas with systemic antibiotics on purely empirical grounds, and some have expressed the opinion that complications have been markedly fewer. Initially severe cases have recovered more rapidly, albeit toxic, with this treatment than less severe cases which have trailed on with malaise and complications where antibiotics have not been used. This has been on purely experimental lines, but, if one assumes that the theory of the starting handle may apply to influenza also, fits into the picture.

B. Autogenous vaccines, however, if properly made, could be used a great deal more than they are. It must be emphasized that none but autogenous vaccines are likely to be of service, as the nasopharyngeal organisms of the general population are very heterogeneous. With the simple technique we used, these are easily made in the laboratory. The weekly dosage—0·1, 0·3, 0·5, 0·5 ml., &c., of a 500 million per ml. suspension—is a nuisance, but the real chronic cold sufferer will put up with anything that he hopes will help, and these are the cases which show most benefit. Several of our volunteers, after having two winters' injections, have been persuaded to try going the next winter without injections and have remained free, suggesting a build-up of immunity.

## Disadvantages

(1) *Autogenous vaccines.*—I know of no drawbacks apart from the tedium of weekly injections. A slight redness at site of inoculation was seen in some cases, but gave no trouble and subsided readily without treatment.

(2) *Antibiotic tablets.*—The only trouble was the incidence of "strawberry" tongue. This seems to be a form of idiosyncrasy as most volunteers were unaffected. It might persist for some time, although the cold itself had cleared up in forty-eight hours or less. The makers of the tablets say that the cause is not yet clear. An interesting point is that the school in our series had no trouble of this kind, which suggested a balanced vitamin diet though the manufacturers have found no connexion with vitamins but favour the glucose angle. The condition was usually mild, having little more than nuisance value except in a very few cases. Possibly reduction in dosage to less than the 15 mg. per tablet might be the answer. When this difficulty has been eliminated the way may be clear to the control of the common cold in industrial establishments.

## BOOK REVIEWS

**Cortisone Therapy.** Mainly applied to the Rheumatic Diseases. By J. H. Glyn, M.A.(Cantab.), M.D., M.R.C.P., D.Phys.Med. (Pp. x+162; illustrated; 21s. 0d.) London: Heinemann. 1957.

When important questions in a new domain of practical medicine remain controversial, and when the literature has become unwieldy, a monograph which critically examines available data can be immensely helpful. In "Cortisone Therapy" Dr. J. H. Glyn attempts an appraisal of the therapeutic value of cortisone, especially in rheumatoid arthritis.

This, however, is not the kind of review that will appeal to specialists. In the light of his own experience he considers the work and views of others, but usually does not tell us who they are: no references are given, and apart from a list of some well-known textbooks, reviews and articles—"for further reading"—there is no bibliography.

It is in fact a synthesis designed for general practitioners.

In an important chapter—"Practical Problems in Cortisone Therapy"—Dr. Glyn considers, among other things, how patients with rheumatoid arthritis are to be selected for prolonged cortisone therapy. He thinks it is indicated in some 15–20% of all cases. It is perhaps not made plain enough that relief is likely to decrease and danger to increase with the passing years.

A short chapter is given to intra-articular hydrocortisone in rheumatoid arthritis; and a well-illustrated and very helpful appendix on the technique of intra-articular injection has been provided by Dr. J. G. Bearn, Lecturer in Anatomy at the Middlesex Hospital Medical School. The use of local hydrocortisone in osteo-arthritis, bursitis, teno-synovitis and other soft tissue lesions, is discussed in a chapter on the use of cortisone in diseases other than rheumatoid arthritis.

The style is apt to be verbose: and his studious avoidance of the first person singular becomes a little tiresome. But with these minor criticisms, the book can be confidently recommended to general practitioners and hospital residents.

**Bronchopulmonary Diseases. Basic Aspects, Diagnosis and Treatment.** By 142 Authors. Edited by Emil A. Naclerio, M.D. (Pp. xxvi+956; illustrated; £8 17s. 6d.) London: Cassell & Co. Ltd. 1957.

This magnificently produced volume of close on a thousand pages consists of contributions upon bronchopulmonary disease from no less than one hundred and forty-two authors, many of whom are among the best known in the specialty. As Overholt states in his foreword, "The early publication in book form of papers prepared by many authors for an immediate outlet in a journal gives broader coverage than the usual type of book and can be more up to date". Indeed, this sentence epitomizes the mode of presentation here. Many distinguished contributors, such as Abbott, Auerbach, Banyai, Barach, Chamberlain, D'Esopo, Harkavy, Jackson, Janes, Lincoln, Mitchell and Samson, write upon the subjects they know best and others fill in the gaps, giving a bird's eye view of respiratory diseases which ranges from embryology to tracheotomy. By and large, the information is up to date and many of the chapters could hardly be bettered. Individual authors have evidently been given a free hand, and editing in the ordinary sense has not been attempted. For example, the chapter upon "The Pneumonias" is divided into three parts, namely a general classification (three pages, no references), chemotherapy in acute pneumonias (ten pages, four references) and lipoid pneumonia (six pages, sixty-two references). This unevenness, which prevails throughout, means that it cannot be used as a book of reference even in the United States, from which country nearly all the references derive. The reviewer was interested to see that no less than six pages are devoted to bronchitis (no references), which is more than usual for an American text book, but the prevalence and consequences of intermittent and chronic bronchial suppuration are still understated.

This tome contains so much information that at least part of it must appeal to anyone interested in disorders of the respiratory system. The unfortunate mode of presentation and the fragmentation into short chapters make it difficult to read. Perhaps it is best regarded as a collection of contemporary articles, almost any one of which is well worth reading on its own.

**Fluid Balance in Surgical Practice.** By L. P. Le Quesne, D.M.(Oxon.), F.R.C.S.(Eng.). (Pp. vii+140: 20s.) London: Lloyd Luke (Medical Books) Ltd. 2nd Edit. 1957

This admirable small monograph was reviewed in these columns some two and a half years ago and now a new edition has been called for and, apart from numerous minor emendations, differs mainly from the previous one in the inclusion of a chapter on fluid balance in children. There is certainly no shortage to-day of books concerning fluid balance and this is a good thing because as a subject it has been neglected for many years. This particular one makes a special appeal to the surgeon and it was indeed originally the prize-winning Moynihan Essay, the main burden of its thesis being the fluid and electrolyte balance of the post-operative patient.

The new chapter written by Dr. Webb provides an excellent epitome of fluid balance in childhood with a very proper underlining of the importance of conservatism at all times when infusing infants and children. Far too many neonatal babies have been drowned by the over-solicitous attention of house officers with intravenous drips; more than have succumbed to dehydration, for a baby at this time of its life is exceedingly well provided against the rigours of limited fluid intake. The rest of the chapter on the giving of fluid and electrolytes to children is clear, concise and thoroughly sound.

Le Quesne's book is pleasant to read, yet provides an excellent background to the newer scientific work in this field. There is a reasoned appreciation of the changes in fluid balance which occur during the administration of adrenal cortical hormones. There is a good account of the anti-diuretic hormone and potassium deficiency finds its place in this work without being unduly stressed as it has been in recent years. There is in addition sound advice concerning the management of renal failure, a problem much to the fore at the present time.

**The Anatomy of Congenital Pulmonary Stenosis.** By Sir Russell Brock, M.S., F.R.C.S., F.A.C.S.(Hon.). (Pp. xiii+114; illustrated; 30s. 0d.) London: Cassell & Co., Ltd. 1957.

Sir Russell Brock is well known as a thorough, fastidious and clear-thinking author and his book on "The Anatomy of the Bronchial Tree" is still a standard work of reference. In this new monograph he writes from an unrivalled experience in treating the condition and each aspect of the subject is considered, be it embryological, historical or that of comparative anatomy.

Sir Russell was the pioneer of the direct approach for treating pulmonary stenosis and perforce had to acquaint himself with the various anatomical varieties which could be encountered. The wealth of illustrations in this monograph demonstrates the various types of infundibular and valvular stenosis which may be encountered and also the secondary changes which take place in the rest of the cardiovascular system. The principles of operative repair naturally figure largely in the text, but this is a work which deals as thoroughly with the anatomy and physiology of the condition as it does with its surgical correction. Many readers may be surprised to find that Sir Arthur Keith had written so widely on this subject and his admirers will be delighted to see a particularly attractive photograph of him forming the frontispiece of this book. Evidence is assembled to show that a controlling mechanism exists in the musculature of the right ventricular outflow tract which controls the flow of blood. This is based partly on the work of Keith and also on observations made on the living patient by the present author.

**Principles of Surgical Physiology.** By Harry A. Davis, M.D., C.M., F.A.C.S. (Pp. xiv+841; illustrated; £7 7s. 0d.) London: Cassell & Co. Ltd. 1957.

This large book of some 800 pages sets out to cover a very wide field of physiology, primarily that involved in surgical practice.

There is of course no such subject as surgical physiology, or at least there should not be; physiology remains the same whether it is read by surgeon, physician or physiologist, but it is possibly a convenience to gather together into one work the sort of physiology which is of most importance to the surgeon. Here will be found good introductions to such subjects as water and electrolyte metabolism, wound healing, tissue transplantation, the pancreas, spleen and so on. There are very well-selected references at the end of each chapter.

This is not a book to be put in the hands of every student, it is rather one which should be placed in the library or the department of surgery.

The book is written much more in the style of a surgical than of a physiological work. This is essentially a work of reference which provides an enormous amount of basic information and is likely to continue through many editions in the future.

**Introduction to Clinical Endocrinology.** By A. Stuart Mason, M.A., M.D., B.Ch.(Cantab.), M.R.C.S.(Eng.), M.R.C.P.(Lond.). (Pp. viii+192; 22s. 6d.) Oxford: Blackwell Scientific Publications. 1957.

This is a brief neat little book and contains precisely what the title states. It is an introduction to clinical endocrinology and there are no references, although the work is well up-to-date and appears to be completely free from the errors which so often appear in a first edition.

There is a good account of the hypothalamus and the anterior and posterior pituitary. The thyroid receives some thirty pages out of the total, which is right in so far as this is the one endocrine gland which provides more clinical material than all the others. The adrenals are well reviewed and primary aldosteronism finds a place in this chapter. The testes and ovary are both discussed in neat little essays and treatment is well described, doses always being clearly indicated.

This is a book primarily written for the newly qualified doctor who wishes to understand more about the subject of endocrinology as he sees it in his patients, but it serves equally well as an introduction for the final year medical student. It is well printed and bound and certainly not expensive at 22s. 6d.

**Benjamin Waterhouse and the Introduction of Vaccination. A Reappraisal.** By John B. Blake. (Pp. 95; illustrated; 32s. 0d.) Pennsylvania University Press. London: Oxford University Press. 1957.

In July, 1800, Benjamin Waterhouse, by inoculating his son with cowpox virus received from England, introduced the practice of vaccination into the United States. Since the latter part of the nineteenth century Waterhouse has been regarded as one of the most notable pioneers of preventive medicine in America. This latter-day praise contrasts strangely with earlier neglect, which has generally been attributed to the antagonism of Waterhouse's contemporaries, antagonism attributed variously to his religion, politics, scientific qualifications or skill in controversy.

This book gives a detailed history of the controversy based on a new analysis of contemporary letters and newspaper files. The picture of Waterhouse that emerges is not only of a controversialist writing numberless letters to the Boston papers attacking his professional colleagues, but also of a would-be monopolist, anxious to reserve the distribution of cowpox virus to those who were prepared to share the profits with him and distribute it no further.

Apart from the principal story the book is interesting for its revelation of the methods of medical controversy 150 years ago. The numerous quotations are fully documented in 17 pages of notes, and there are three illustrations of letters; many general readers would surely have preferred a portrait of the "hero". But at 32s. 6d. the book can hardly be for the general reader.

**The Early Diagnosis of the Acute Abdomen.** By Sir Zachary Cope, B.A., M.D., M.S.Lond., F.R.C.S.Eng. 11th edit. (Pp. 188; illustrated; 18s. 0d.) London: Oxford University Press. 1957.

This wonderful little book first appeared thirty-six years ago and Sir Zachary Cope has now almost entirely rewritten it and provided new illustrations. This book presents exactly the information which its title promises and does it so clearly and thoroughly that it is as well suited to the medical student as to the specialist in surgery. Certainly it has a particular appeal for the general practitioner and it would be hard to find a book which distils more wisdom more clearly in so few pages. The Oxford University Press are also to be congratulated on making the book so much more attractive in its latest edition.

**Artificial Insemination in the Human.** By A. M. C. M. Schellen, M.D. (Pp. xii+420; illustrated; 72s. 0d.) London: Cleaver-Hume Press. 1957.

This book covers the entire field from the history of A. I. to the ethics of A.I.D. It quotes everything everyone has ever done or said on the subject, to the embarrassment of many whose *obiter dicta* of past years were best forgotten. It is an anthology of the subject rather in line with Sutton's "Diseases of the Skin", and gives at the end of each chapter a complete list of world references. The indications for A.I.H. are given briefly but completely, including retrograde ejaculation, which has been dealt with successfully by Hotchkiss and others. In the indications for A.I.D. the author rightly points out the

great difficulty in declaring a case of gross oligospermia infertile to the point of sterility and hence advising donor insemination. In a series of cases elsewhere pregnancies have been reliably reported from counts as low as 500,000/ml. It is interesting to note the replacement of the cumbersome term oligozoospermia by oligospermia and the substitution of hypospermia for deficient volume.

There follows an excellent and comprehensive chapter of 68 crowded pages on the technique of A.I. The reason for the poor results in A.I.H. is perhaps not sufficiently stressed—it is of course entirely due to the poor quality of the semen. A.I.H. makes the best use of a poor specimen. Ways of improving these results are enumerated, stress being placed on the possibilities of freezing repeated "split" ejaculates, in cases of oligospermia, and finally thawing and pooling to build up a more nearly fertile specimen. Centrifuging is mentioned here and some workers still report on it enthusiastically but most have discarded the device, preferring to employ the first part of "split" or partitioned ejaculates.

As to collection of semen specimens, epididymal puncture is dismissed as rarely successful and so is vesicular massage, but the latter can be properly managed if the technique is understood and must remain until electrical induction is perfected and the apparatus made less costly. The dangers and advantages of the semen bank and donor pool, largely an American idea, are recounted. The practical part of the book ends with the timing of ovulation and the risks resultant on errors of technique.

The second part of the book is largely devoted to the vexed subject of A.I.D. and, following the recent controversy in England, will clearly need a new chapter. In turn it deals with the choice and selection of the donor, precautionary measures for the protection of the specialist and the consenting parties and the many and varied forms used by specialists all over the world are printed. These make interesting reading. A valuable chapter is given to comparison of adoption with A.I.D.; even the Press reactions of different countries are included.

**Connective Tissue.** A Symposium Organized by The Council for International Organizations of Medical Sciences. Edited under the direction of R. E. Tunbridge. (Pp. xii + 371; illustrated. 42s. 0d.) Oxford: Blackwell. 1957.

This symposium was held in London in 1956 under the auspices of the Council for International Organizations of Medical Sciences. Some thirty participants attended, and their contributions and group discussions are given *in extenso* in this monograph.

In general, the contributions centred mainly upon biochemical questions, and more particularly on the origins and constitution of the various fibrous elements and the ground substance of the soft connective tissues. Many of them are highly specialized, but several, notably those of Fitton Jackson, Schwarz and Robb Smith, which deal with the morphology and differentiation of the various types of fibre, will be of particular interest to pathologists and to clinicians concerned with rheumatic diseases.

The book provides an authoritative review of fundamental work in a field of medicine that in recent years has attracted particular attention as a result of efforts to establish a nosological entity from the "collagen diseases". Its perusal makes manifest the great progress that has been made in knowledge of the soft connective tissues since electron-microscopy and the newer biochemical tehcniques of protein chemistry have been applied to its study.

**Chronic Illness in the United States.** Volume 1: Prevention of Chronic Illness. Commission on Chronic Illness. (Pp. xxii+338; 48s. 0d.) Harvard University Press. London: Oxford University Press. 1957.

This book fulfils a useful purpose in drawing attention to the clinical, social and economic significance of chronic disease perhaps better designated, disease of chronicity. The important aspects of prevention, care and rehabilitation of the disabled is given prior place with good effect. This is the first volume of a 4-volume report dealing with chronic illness in the United States. The promotion of health, the prevention of selected chronic diseases such as arthritis and rheumatism, cardiovascular disease, tuberculosis, cancer, diabetes and blindness, all receive due attention and certain conclusions and recommendations are made which are extremely apt and helpful.

The book should be of great value to medical and social workers in this sphere and the suggestions made for further research are extremely helpful.

## DISCUSSION ON THE MOUTH-BREATHER

**Mr. E. Gwynne-Evans** (London):

*The Mouth-breather and the Muscular Seals of the Oral Cavity*

Nasal breathing depends on the patency of the nasal passages and on the orofacial muscles closing and sealing off the oral cavity from the nasopharyngeal airway.

Mouth breathing due solely to gross nasal obstruction is comparatively rare; treatment is usually straightforward, depending on the recognition and removal of the cause. Mouth breathing due primarily to failure of the orofacial muscles is relatively common; little or no nasal obstruction may be present; lines of treatment vary; most are unsuccessful.

This paper is devoted to the mechanisms operating the anterior and posterior seals of the oral cavity in breathing and feeding. The functions of breathing and feeding are inseparable in any consideration; brief references will be made to:

(*a*) The evolutionary history of the air and food passages, the jaw and facial muscles.

(*b*) The developmental anatomy of the air and food passages; the face and neck region.

(*c*) The changes in orofacial behaviour that take place as the central nervous system matures.

*The Comparative Anatomy of the Air and Food Passages*

The researches of Sir Victor Negus show that differences in structure among the species are associated with varying requirements. In most mammals, the tongue lies flat in the mouth; the larynx lies just behind the mouth well forward in the neck and is related to the level of the basi-occiput, not to the cervical vertebræ, as in man. Mammals depending on their sense of smell have a special fibrocartilaginous flap—the epiglottis—standing up in front of the laryngeal aperture. This flap either overlaps the free margins of the soft palate as in deer, or extends upward into the posterior opening of the nasal channels as in whales and dolphins. This arrangement effectively prevents breathing through the mouth and ensures the drawing in of air over the olfactory nerve endings. In man the jaws lie under the cranium; the tongue is "bunched up", arched and displaced backward so that it curves downward into the pharynx. The larynx lies below and at right angles to the line of the mouth, opposite the cervical vertebræ. The epiglottis is separated from the soft palate and the seal to prevent oral breathing is lost. However, the soft palate lies passively over the posterior convex surface of the tongue and in certain circumstances close coaptation of the soft palate and tongue will prevent mouth breathing.

Food has to be transferred from the mouth to the gullet past the larynx with a minimum of interference to breathing.

In man the epiglottis is tipped over the aperture of the larynx to form a chute for the passage of the food. Breathing ceases momentarily when the sphincteric girdles of muscle close the nasopharyngeal and laryngeal apertures respectively and the sphincter surrounding the upper end of the œsophagus relaxes to allow the food through. As swallowing is intermittent and rapid there is very little interference with breathing. In herbivoræ the epiglottis is well developed, overlapping the soft palate and its lateral folds. The upstanding lateral margins of the epiglottis give protection to the laryngeal aperture. For long periods semi-liquid food passes on either side of the larynx almost continuously into the gullet between the ary-epiglottic folds and the lateral walls of the pharynx. Overflow into the larynx is prevented, interference with breathing is avoided and the sense of smell, particularly for the detection of enemies, is thus in use throughout the feeding period. Although man is never dependent on the sense of smell, the demand for continuous and uninterrupted nasal breathing when feeding is just as insistent in early infancy. The rhythm of suckling once initiated tends to continue for minutes at a time unless deliberately interrupted. Free and continuous nasal breathing throughout the suckling period is therefore vital.

*The Functional Anatomy of the Infant Oral Cavity*

In infancy the vertical space between the gums is filled by the arched tongue, which contacts the inner surface of the cheeks, the hard and soft palate. The anterior margin of the tongue is broad; there is no tip and it cannot be protruded far or swept from side to side; it is used exclusively for pumping and squirting milk into the pharynx in suckling or for passing fluids otherwise placed in the mouth by sliding them backward and downward into the pharynx.

The high level of the tongue in the infant oral cavity is associated with a high level of the larynx in the neck. Although there is no actual contact of the epiglottis with the soft palate, the close proximity of the larynx to the mouth enables the upstanding lateral folds of the epiglottis to direct the flow of milk around the larynx without inundation of the glottic aperture. The close relationship of the tongue and palate is necessary for suckling. Slow motion cine films have shown that a rubber teat placed on the dorsum of the tongue is repeatedly compressed against the hard palate and rolled out from before backward by successive waves of contraction in the transverse fibres of the tongue. A cine radiographic loop of film showed a rhythmical tensing of the soft palate against the posterior surface of the tongue. Its action seemed to direct the passage of the milk downward toward both lateral food channels of the pharynx and, at the same time, to maintain a free nasopharyngeal airway for continuous breathing. There were times, however, when the soft palate flicked upward as if to close off the nasopharynx, but, on the whole, the manner of feeding and breathing seemed to resemble very closely the feeding and breathing behaviour of herbivorae as described by Negus. Only with the swallowing of accumulated fluids and later a bolus of food, are the sphincteric systems of the pharynx and larynx utilized.

The lips take no active part in suckling other than forming an effective seal between the infant oral cavity and the breast or rubber teat of a feeding bottle. At rest, they relax; they may or may not be in contact. Lip closure is not an essential requirement; nasal breathing is the rule because the oral route is effectively sealed by the muscular barrier set up by the coaptation of the tongue and palate.

*The Developmental Anatomy of the Child's Oral Cavity and Neck Region*

As the infant grows up an elongation of the lumbosacral segment of the vertebral column and a general increase in the size of the pelvic cavity allow the abdominal viscera to descend. At the same time, the levels of the shoulder girdle and thoracic cage descend to reveal the cervical segment as a neck. The viscera of the neck, viz. the tongue and larynx, are also lowered. The tongue, no longer needed for suckling and already curving backward and downward into the pharynx, descends with the larynx far enough to make way for the downward growth of the maxilla from the base of the skull. The lower level of the tongue and larynx in the neck allows the tongue more freedom to move in the oral cavity for the gathering and passing of food between the erupting teeth which come gradually to fill the vertical space between the margins of the jaws.

In some children, the seal between the soft palate and tongue is preserved; in others, the tongue falls away from the palate and the seal is broken. Should the lips be apart and the mouth be open, in the former case nasal breathing will be the rule, in the latter, mouth breathing will supervene in addition to nasal breathing.

*The Evolutionary History of the Jaw and Facial Muscles*

In some activities of the orofacial muscles, as in suckling, sipping or drinking, they behave in a rhythmical manner as do other muscles of the vegetative or visceral system. In other activities, as in speech, they behave in a highly versatile and complex manner as do other muscles of the somatic system. Referring to the evolutionary history of the jaw and facial muscles, it is significant to find that the branchial muscles of the fish, although striated, are innervated through special cranial nerves belonging to the visceral motor system, not like other striated muscles which are supplied through the somatic nervous system. Higher up the evolutionary scale it is seen that much of the striated visceral musculature has abandoned the gut lining to serve the jaws. Other surviving branchial elements serve a series of aberrant functions as shoulder, neck and facial muscles. In land vertebrates, the constrictor of the hyoid is the only superficial muscle remaining in the neck region. In mammals, it extends as a thin sheet over the surface of the head to form the facial muscles, concentrating in bands round the orbits, outer ears and lips. The purpose of the facial muscles is primarily to control these apertures—not by sphincteric action but by an opening and closing arrangement of the muscle fibres. Man, in common with herbivoræ, has well-developed muscles forming the lips and cheeks. The history of their visceral origin is linked with their main purpose—that of receiving and keeping food in the mouth for chewing. Other functions are grafted on later as a side-effect.

*Changes in Orofacial Behaviour as the Central Nervous System Matures*

From the works of Tinbergen and others, it is now realized that groups of muscles are co-ordinated from within an hierarchically organized central nervous system to carry out special movements for locomotion, feeding or hunting &c., which are characteristic of the species and necessary to the maintenance of the individual. Experiments have shown that they are innate and "triggered off" by appropriate stimuli from the outside world. Once the in-born or unlearnt response is modified, however, and a more precise adaptation to environment is made, learning processes are involved. As these progress, it soon becomes difficult to distinguish between unlearnt and learnt behaviour.

Suckling is an innate pattern of behaviour. The taking of food from a spoon, the thrusting of food by the hand into the mouth, the biting and chewing of food—all require different patterns of muscle co-ordination concerned with the basic function of feeding. They are not learnt, but appear in succession as fresh neuromuscular pathways are opened up by the normal processes of maturation. With practice, more precise movements are achieved automatically; modifications of feeding behaviour acceptable to good-mannered society are learnt—and these, like all cultural patterns, come the hard way.

In early infancy, the tranquillity of the face is frequently disturbed by emotional outbursts when all the muscles attendant on the lips contract as an entire group without discrimination to stretch the mouth widely open. Passive relaxation allows the lips to return to their usual position of rest; they may or may not lie in contact; the facial mask is expressionless and one of innocent repose. Total behaviour, typical of an immature central nervous system, gives way to selective behaviour in which the lips may assume a variety of shapes. It is difficult to say how far these movements are "in-born" and come from "within" in response to a particular situation or are acquired by imitating other individuals. However, as mental attention is directed toward the orofacial muscles their behaviour is increasingly modified to express the finer feelings and the growing intellect. The unfolding of inherited characteristics brings about further modifications of the facial mask, and it soon becomes even more difficult to say how far the features should be accredited to nature or to environment.

Mental attention constantly invokes lip closure, but in repose the lips will relax to their normal position of rest—in contact or apart; if apart, it is usual to find that as the personality and character of the individual develop, lip closure is eventually embodied in the more mature facial mask of the growing adult without the need of conscious effort. There are, of course, exceptions to this desirable state of affairs, for instance, the personality and character of the individual may not contribute toward lip closure in repose; or structural imperfections, such as a short everted upper lip or a marked discrepancy in the antero-posterior relationship of the jaws and teeth may make lip contact difficult or impossible to achieve.

*Clinical Assessment of Facial Appearances*

Some faces in repose embody lip contact; their outlook on life appears attentive. Some do not embody lip contact; the lips lie more naturally apart than together; moreover, the mouth may be open, often widely.

The lack of awareness in the facial appearance of the last-mentioned children has been attributed to dullness of intellect secondary to adenoid overgrowth, nasal obstruction and inadequate oxygenation of the tissues. Experience shows, however, that a low level of mental ability is not usually found, that the adenoids are not necessarily causing nasal obstruction and that the open mouth is not always indicative of mouth breathing.

This paper is concerned with other explanations of the clinical picture. At one time, the jaw muscles were wrongly classified with the anti-gravitational muscles; it was thought that the open mouth was due to lack of resting tonus in the jaw muscles and a consequent sagging of the mandible. General measures and special exercises prescribed with the idea of increasing muscular tone failed to maintain a closed mouth at rest. Again it was thought that the open mouth was due to a faulty habit of co-ordination among the orofacial muscles. Attempts were made to re-educate the muscles in correct habits of co-ordination. Special exercises in the form of games were prescribed to encourage a proprioceptive sense of contact between the lips. Dental appliances such as the Andresen monobloc (a form of intra-oral screen) were employed to provide the child with a sensory pattern or a "mental image" of a closed mouth. These measures also failed to inculcate a habit of lip and mouth closure at rest.

It soon became apparent that the facial mask, whatever the appearance, is innate to the individual and resists change by any means.

No two faces are exactly alike except perhaps those of identical twins. Yet, there are many "types" of faces with similar variation of soft tissue morphology that come well within the widely accepted limits of what might be called "a normal face". The opinion is now held that the concept of "normal variation" should be broadened to include the facial type whose mouth is usually open when the child is at rest. In this type it is not that the mouth cannot be kept closed at will but that when the face is in repose, the jaw and facial muscles will inexorably relax to the open position which, as Professor Ballard states, is the "innate resting position" and therefore normal for the individual. Perhaps the truth of this concept might be better understood if the converse type of face be considered. In this case, it is natural for the lips to be together and the mouth closed in repose; constant mental effort will be necessary to keep the lips apart and the mouth open; the closed position is innate to the child and therefore normal for him.

Facial appearances give little or no indication of mouth breathing or of nasal obstruction. Taking the "open mouth" type of child first; an inherent coaptation of the tongue and soft palate will sometimes persist and still prevent mouth breathing. Mouth breathing will only occur when (*a*) the soft palate is elevated from the tongue in order that breaths may be drawn deliberately through the mouth because of nasal obstruction, or (*b*) the tongue lies naturally away from the soft palate whether nasal obstruction is present or not. It is significant that when nasal obstruction is present, correctly diagnosed and treated, with restoration of a free nasal airway, this type of facies remains unchanged apart from any influence the progress of maturation may have later on facial appearances. Referring to the "closed mouth" type of child, an inherent contact of the lips will prevent mouth breathing. The presence of nasal obstruction, however, is not ruled out; an intermittent and often imperceptible parting of the lips and separation of the tongue and soft palate will allow adequate mouth breathing if necessary. It is again significant that when nasal obstruction is present and removed, a closed mouth with lip contact is immediately resumed in this type of child.

Mouth breathing must be sought for in every child and if found to be present, the primary cause should be ascertained. The best way to test for mouth breathing is to hold in front of the mouth a cold polished metal tongue spatula to obtain condensation of breath and visual proof. The capacity for nasal breathing can be assessed in the same manner. Anterior rhinoscopy is necessary to reveal the state of the mucosa and to exclude the commonest cause of persistent anterior nasal obstruction, viz. chronic œdema of allergic origin. Soft tissue lateral radiographs of the entire pharynx are necessary to demonstrate the presence of adenoids, possible overgrowth and obliteration of the post-nasal space; also, to show the position and relationship of the tongue and soft palate at rest.

*Conclusion.*—It is preferable to institute measures to ensure healthy and free nasal passages than to worry unduly about facial appearances and to submit the child unnecessarily to the wearing of dental appliances, to tedious lip exercises or to the injustice of constant admonitions to keep the mouth and lips closed.

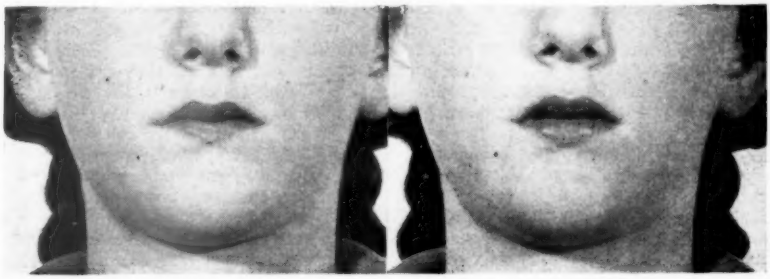
**Professor C. F. Ballard** (London):

*Mouth Breathing*



In 1929 Brash said: "There is no satisfactory proof that the presence of adenoids, the diminution or absence of nasal breathing or the constant habit of mouth breathing can affect the form of the jaws or the position of the teeth in any of the ways that have been suggested. It has still to be proved that there is any significant correlation between the presence of adenoids and the incidence of deformities of the jaws and palate."

For more than fifteen years a group of us have been studying the relationship between (1) jaw form, (2) soft tissue morphology and (3) the behaviour of soft tissue morphology in relation to malocclusions and upper respiratory conditions. Our observations have not only confirmed what Brash said, but have by inductive reasoning demonstrated quite clearly that mouth breathing does not produce deformities of the jaws and malocclusions, and does not result in the development of the adenoidal facies. Our studies necessitated detailed classification of variations of the form of the jaws, of the morphology of soft tissue, of the patterns of activity of the soft tissues in the production of anterior and posterior oral seals, and in mastication, speech and expressive behaviour.

Our longitudinal studies based on this classification have shown that the orofacial morphology remains remarkably constant during growth. It does not change in the ways that would be necessary to produce an adenoidal facies, with the associated deformities, as a result of nasal obstruction and mouth breathing. Further, detailed classification has shown that as we bring more individuals into a cross-sectional study distinct types fade and the picture becomes more that of a smooth distribution of variations.

In my view this is an indication that we are in fact not dealing with abnormalities arising as a result of environmental conditions but with variations determined by inheritance.

It would be advantageous at this stage to describe some of the variations of soft tissue posture and activity that Mr. Gwynne-Evans has mentioned. Firstly the lips-closed posture or, as it is now called, competent lip morphology. The individual maintains an anterior oral seal without muscular effort (Fig. 1A). The mandible is in the innate postural position

A B

FIG. 1.—Competent lip morphology. A, Maintaining anterior oral seal with muscles in their innate posture. B, Mandible and tongue dropped from innate posture to produce an oral airway.

and the muscles of facial expression are similarly postured. The tongue almost fills the oral cavity and posteriorly contacts the soft palate and maintains a posterior oral seal. If individuals with such a combination of morphological features have nasal obstruction an oral airway is produced by dropping the mandible to part the lips (Fig. 1B) and by dropping the tongue away from the soft palate. It does not matter for how long they have to maintain mouth breathing, they do not develop an adenoidal facies or lips-apart posture.

Now for the lips-apart posture or so-called adenoidal facies (Fig. 2B). The mandible

A B

FIG. 2.—Incompetent lip morphology. A, Circumoral contraction to produce an anterior oral seal. B, Lips apart, mandible and facial muscles in innate posture.

gain is in the innate postural position and the facial musculature is in its innate posture. In order to produce an anterior oral seal these individuals have to contract the circumoral muscles to a degree which might be so slight that it is not detectable by the uninitiated observer, or it may be so extreme that it spoils the individual's facial appearance (Fig. 2A). This open-lip posture is not due to lack of tonus, it is not produced by dropping the mandible from the innate posture and does not arise as a habit because of the constant necessity for oral breathing. Furthermore as has been previously reported (Ballard, 1952; Gwynne-Evans and Ballard, 1948) the majority of individuals with this lips-apart posture are not mouth-breathers because the posterior oral seal is intact. This can be demonstrated clinically and radiographically. Still further support for our conclusions comes from our early attempts at re-education as we called it; these failed and it was because they did so, uniformly, that we delved more deeply into the physiology and genetic background of posture and motor activity (Ballard, 1955).

Our observations have demonstrated in detail the morphology associated with the findings of Warwick James and Somerville Hastings (1932) that the open lip posture is not necessarily associated with mouth breathing. Warwick James and Somerville Hastings regarded the tongue soft palate contact as a posterior oral sphincter. It is this open-lip type which results in such statements as "the adenoid facies may be met with in children without adenoids".

These facts on the relationship of variation of soft tissue morphology to mouth breathing should be enough in themselves to destroy the theory that mouth breathing can produce narrow nasal passages, underdevelopment of the mouth and general arrest of growth, V-shaped alveolar arches and crowded teeth. Unfortunately, however, these varieties of skeletal morphology do occur together and frequently in association with the lips-apart posture. Therefore further discussion is necessary. As has just been stated, however, there is no cause and effect link with mouth breathing.

Longitudinal studies of the growth of the facial skeleton have been in progress for a good deal longer than our longitudinal studies of soft tissue development partly because of the ease with which the patterns could be recorded radiographically. Brodie (1940) reported on a serial study of growth of the face and his conclusions indicate that even in cases of extreme variations of the skeletal morphology, the so-called abnormal, the patterns were established soon after birth and thereafter developed in an orderly manner, the general pattern of each case remaining the same.

Our longitudinal studies and assessments of morphological types confirm these findings. We do not find any particular type of morphological pattern associated with mouth breathing; all types may suffer from chronic nasal obstruction. We do not see a change in shape or size of the jaws with chronic nasal obstruction and mouth breathing as would be expected, and we do not see changes towards a "normal" after relieving nasal obstruction. Further and strong support surely comes from reported cases of complete nasal atresia—to quote Thomson *et al.* (1955): "It is noteworthy that this complete atresia of the nose even with entire mouth breathing does not entail the chest deformity, narrow nostrils, alar collapse, deflection of the septum and changes in the ears which are frequently attributable to partial nasal stenosis."

With regard to the chest deformity it is quite possible that there may be an association between the type of facial morphology which has been labelled adenoidal and flat chest with winged scapulæ because the open-mouth posture may be shown by investigations in progress at the moment to be more common in the individuals high in ectomorphy.

Putting all the facts together, and they include evidence not mentioned on the inheritance of orofacial variations, I would state quite definitely that orofacial morphology is mainly inherited and is not so amenable to environmental influences as the mouth-breathing adenoidal facies concept requires. If this is so, what is our approach to treatment both for the open-lip position, the true mouth-breather and the malocclusions associated with these variations?

To deal firstly with the malocclusion that may be present. Prominent upper incisors may result from a combination of the following inherited features in a typical case.

(1) Open-lip posture.

(2) Crowding in the maxillary arch.

(3) A skeletal morphology which has resulted in the mandibular dental base being post-normal to the maxillary dental base.

The consequence of this combination of features is that the lower lip is behind the upper incisors at rest and in many cases an anterior oral seal is produced by contracting lower lip against tongue, the upper lip being comparatively inactive.

The orthodontist cannot change growth patterns and therefore cannot change jaw relationship. What can be done, however, is to bring the upper incisors lingually and inside the lower lip after reduction of the number of teeth in the maxillary arch. This treatment is most satisfactorily carried out by the extraction of the upper first premolars when they erupt (at about 10 to 11 years). Then by orthodontic treatment the upper incisors are brought inside the lower lip enabling the individual with incompetent lip morphology to produce an anterior oral seal with far less muscular effort, and in some cases greater use of the upper lip results. However, in other cases the innate open-lip posture remains and some training is required to establish a habit posture of lip seal. It is important to differentiate between innate posture and a habit posture (Ballard, 1955) if the aim of the training is to be appreciated.

Our clinical approach is as follows: We have found, as Mr. Gwynne-Evans has said, that an attempt to induce the maintenance of an anterior oral seal as a habit posture in young children is frustrating both to the child and the parents. Lip exercises and games are of little avail and a waste of time. The child is left alone to develop naturally until the time that orthodontic treatment is indicated. Following orthodontic treatment a fair percentage of children by the application initially of some conscious effort induce a habit posture of lip closure which is later quite possibly maintained reflexly as a result of sensory contact of lips. In some individuals the tongue comes into the production of an anterior oral seal making contact with the lower lip. In other individuals the degree of incompetence is such that they have to apply considerable conscious effort in the maintenance of an

anterior oral seal. Many of these report that they know their lips do not stay together at night and in fact in such cases they are frequently apart during the day, particularly when conscious effort relaxes in moments of interest or excitement, &c. In the extreme, there are the cases in which the degree of incompetence is such that the maintenance of an anterior oral seal requires a greater effort than can be maintained consciously, such a muscular effort in fact spoiling the facial appearance.

To sum up: In these cases the open-lip posture is not a habit but the lips-closed one is, and as the degree of incompetence increases so the degree of mental effort to produce the habit is greater. At the same time, age and environment of the individual have to be taken into account when suggesting the application of conscious effort in the production of the habit posture.

Lastly there is the case of the true mouth-breather due to inherited incompetence of both anterior and posterior oral seals. If the physician or otorhinologist believes that oral respiration is a contributory factor in the maintenance of an upper respiratory infection then it is possible to control nasal respiration during the night by means of the insertion of an oral screen as has been illustrated by Scott-Brown (1952) and many dental textbooks, or the monobloc appliances which will fit on the lingual sides of upper and lower dental arches round the tongue induce mouth closure reflexly in some cases.

It is frequently stated that long-standing nasal obstruction results in loss of instinct for nasal respiration and the individual continues to mouth-breathe and has to be re-educated. This is not so. The idea has arisen because, when nasal obstruction is cleared by the removal of adenoids, in those cases with the open-lip posture, the individual still has the open-lip posture post-operatively. When adenoids are removed for the reason that the child is mouth-breathing as diagnosed from the lips-apart posture, loss of instinct is given as the reason for the persistence of the lips-apart posture. However, in those cases of nasal obstruction with the innate lips-closed posture, no re-education is required. The individual reverts immediately to nasal respiration and it is so even with the open-lip posture if the posterior oral seal is innately competent. In 1955 I discussed the biological background to instinctive and habit orofacial behaviour and gave my reasons for believing that habits do not displace innate patterns in the central nervous systems as readily as the loss of instinct theory would require.

I have already mentioned that a cross-sectional study might show a correlation between the lips-apart posture and the body type high in ectomorphy. It might also be possible to demonstrate a correlation between the lips-apart posture and the incidence of asthma, upper respiratory infection and even appendicectomy and myopia. This may seem on the face of it absurd but I should like to refer you to a paper by Wallis (1953). He investigated the connexion between post-normal occlusion and general health, enlarged tonsils and adenoids, chest diseases and deformities, &c. Post-normal occlusion is in our population frequently associated with the lips-apart posture so his conclusions are of interest here. Briefly, he found a correlation between post-normal occlusion and a greater tendency to suffer from birth onwards from a large number of disorders. From this correlation he postulated a general biological inferiority of the post-normals. He reasoned that this might explain why collections of skulls of 400–500 years ago showed a low percentage of malocclusion. Those with post-normal occlusions being biologically inferior did not survive the very high infant mortality rate. In my opinion further investigations on these lines might be profitable.

## Conclusion

In my view the theory of adenoidal facies has resulted from a purely subjective approach and a lack of knowledge of the extent of inherited variations. I should also like to be so bold as to suggest that if our observations are sound and can be applied to the remainder of the body then much time is probably being wasted and feelings of frustration induced in parent and child by treatment or training and perhaps unnecessary surgical procedures performed because the extent of genetically determined variations in our population is not appreciated. Attempts are being made to change innate characteristics of posture and motor behaviour and these impose physiological and mental strain on the individual.

[*November* 22, 1957]

**Three Cases of Cherubism** (One previously shown in January 1954).—A. WHITE FRANKLIN, M.B., F.R.C.P.

*Case I.*—R. M., male, born 10.6.48. Noted by his mother to have a swollen face at the age of 3 years. When seen aged 5 years he had the typical facies of cherubism and had shed his permanent lower central incisors. His case was reported to the Section in 1954 (*Proceedings*, **47**, 543). Since then the swelling has somewhat diminished, but there is gross deformity of the hard palate with indistinct speech (Figs. 1, 2 and 3).

FIG. 1 (*Case I*).—Shows swelling of jaws and elevated appearance of eyeballs.

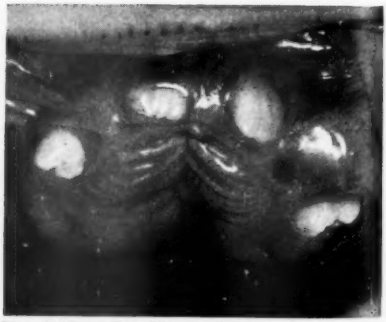

FIG. 2 (*Case I*).—Shows absence of permanent teeth and downward swelling of the maxillæ.

FIG. 3 (*Case I*).—Shows typical fibrous dysplasia of both jaws with irregularity of the few remaining teeth.

*Family history.*—In 1954 the mother reported a negative family history. She now says that her own father had a very full face as did she herself in childhood. Her father could pick teeth out of her jaw with his fingers. X-ray of the mother's lower jaw shows some areas of rarefaction which are compatible with past fibrous dysplasia. Her eldest child, a girl of 13 years, is normal, but another daughter (Case II) is developing cherubism.

*Case II.*—G. M., female, born 18.9.53. She is in other ways a normal, healthy girl. When examined in January 1954 she looked normal. X-rays of the jaws were normal. From the age of 2 years the mother noticed increasing swelling of the lower face. She has the same palpable nodules (lymph nodes) over the mandible as her brother (Case I). Dentition is so far normal. Skull X-ray (2.11.57) shows the characteristic picture of "fibrous dysplasia" of both jaws (Fig. 4). Clinically she might pass as a normal girl were the family history not known. There is the beginning of upward-looking eyes (Fig. 5).

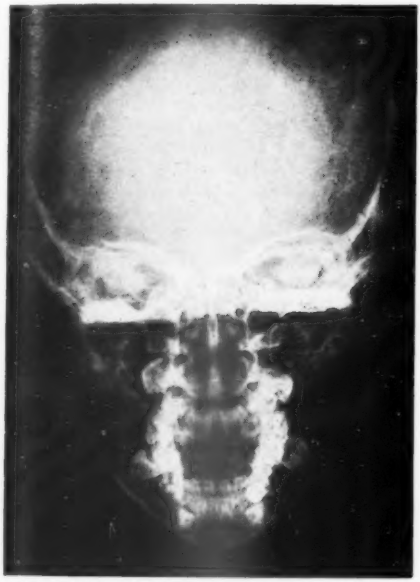

FIG. 4 (*Case II*) (antero-posterior).—Shows fibrous dysplasia of both jaws.

FIG. 5 (*Case II*).—Shows fullness of lower half of face; the eyes appear normal.

FIG. 6 (*Case III*).—Semi side of face shows fullness of lower half of face and eyes normal.

FIG. 7 (*Case III*) (antero-posterior).—Shows fibrous dysplasia of both jaws.

*Case III.*—J. K., male, aged 3 years (Mr. W. H. Maitland Smith's case). Was noted to have an enlarging face at age of 2 years 3 months. He has the typical swelling of the lower face, but eyes are not upward-looking (Fig. 6). X-rays of his jaws show loss of teeth and typical fibrous dysplasia (Fig. 7). He is entirely normal and well in all other respects. The grandmother was operated on for a swelling of the face when she was 17 years old.

*Discussion.*—Case I demonstrates the progress of an established case. Although there is the disability of indistinct speech, it is not at present proposed to operate to remove the excessive soft bone. Case II is in an early stage but it is possible, if it be accepted that the mother had this condition herself in childhood, that the child will not have so severe a deformity as her brother. She may be developing the characteristic appearance of the eyes. Case III, who is well established as regards jaw changes, has definitely normal eyes. The peculiar appearance of the eyes, together with fullness of the face, has led to the use of the name "cherubism". There is some attempt to give up this name and substitute the more general title of "fibrous dysplasia of the jaws". In the author's opinion this would be a pity as the name is a suggestive one and therefore clinically useful.

**Malignant Hæmangioendotheliomata Simulating Miliary Tuberculosis and Neuroblastoma of the Adrenal.**—JOHN LORBER, M.D., M.R.C.P., and A. G. ACKERLEY, F.R.C.S.

Girl aged 3 years, the only child of healthy parents.

1.6.57: She developed painless hæmaturia which became of increasing severity in the next few days. Ten days later she had severe abdominal pain and the hæmaturia continued. A radiograph of the abdomen was reported as negative. On cystoscopy blood was seen to come from the left ureter. An intravenous pyelogram showed dilated calyces on the left side. Whilst carrying out these pyelograms miliary opacities were observed in the lung fields. The presence of densely scattered miliary opacities in the lungs was confirmed on radiograph of the chest, but intradermal tuberculin tests were negative up to a dilution of 1/100 (Mantoux). She was afebrile and her C.S.F. was normal. It was felt wise to treat the child with 0·5 gram of streptomycin and 200 mg. isoniazid daily.

In the course of the next six weeks her condition deteriorated and she became anæmic.

No tubercle bacilli could be found at any time from the urine, from gastric washings or from sputum. The miliary shadows on radiographs of the chest became coarser.

In view of the negative tuberculin test, the absence of bacteriological confirmation and the failure to respond to antituberculous treatment the diagnosis of miliary tuberculosis was now in doubt and among other possibilities a neoplastic left kidney with secondary deposits in the lungs was considered.

14.8.57: She was transferred to the Department of Child Health, Sheffield. On admission, she was very pale (Hb 52%); her liver was enlarged to 4 fingerbreadths below the costal margin, but appeared smooth and was not tender. She had two very dark subcutaneous nodules just below the right scapula. There were no choroidal tubercles. On review of the earlier radiographs it was noticed that there was a patch of irregular calcification in the region of the left adrenal which was distinct from the miliary lesions in the lungs visible in the near vicinity. In addition, the left renal shadow as shown on the pyelogram was thought to be rotated and pushed away from the mid-line. In view of these additional findings a provisional diagnosis of neuroblastoma of the left adrenal was made and the miliary shadows in the lungs, the enlargement of the liver, the hæmaturia and the subcutaneous nodules were thought to be due to secondary deposits. The skin lesions were removed for histological study but were not diagnostic. The bone marrow was examined for evidence of neuroblastoma or other malignant cells and before the results of these investigations were known treatment was begun by intramuscular injections of 2 mg. vitamin $B_{12}$ daily for seven days and followed by the same dose on alternate days (130 mg./kg.). She was also given supportive transfusions. Investigations relating to tuberculosis were repeated, all with negative results, including tuberculin test with concurrent intradermal injection of cortisone (Citron and Scadding, 1957). The result of the bone-marrow examination was negative.

24.8.57: She had a succession of major convulsions. The C.S.F. after this episode was uniformly blood stained and all the changes in it could be attributed to intracranial hæmorrhage (R.B.C. 9,500, W.B.C. 600, protein 320 mg.%, sugar 62 mg.%). It appeared that she now had secondary deposits in the brain.

As no histological diagnosis was yet available, it was decided to perform a laparotomy (Mr. R. B. Zachary) on 28.8.57. The liver was found to be enormously enlarged and was studded with deep red-coloured tumours. A piece was removed for section.

The kidneys could not be seen, but a mass was felt in front of and above the left kidney.

Following this she generally became weaker and died on 10.9.57.

*Necropsy.*—A mottled vascular and grey mass approximately 4 cm. diameter was present at the upper pole of the left kidney. It was adherent to the spleen, infiltrated the diaphragm

FIG. 1.

and extended through the kidney substance to the renal pelvis which was surrounded by hæmorrhage. The left adrenal was not identified, but calcification was palpable in this region of the tumour. This was confirmed by a post-mortem radiograph (Fig. 1). The right kidney and adrenal showed several small, deep red, cystic nodules. Each ovary was slightly enlarged and contained central bluish-red hæmorrhagic tissue, but had an intact capsule. The liver (Fig. 2) was grossly enlarged without cirrhosis, and contained very many discrete red areas (0·2–2·5 cm. diam.), the largest with visible vascular spaces. Scattered red nodules were present on the peritoneal aspect of the intestine and in the marrow of the lower lumbar vertebral bodies. The lungs were studded thoughout with a multitude of small hæmorrhagic nodules (0·1–1·0 cm. diam.), some having brown centres.

The leptomeninges and brain contained red lobulated blood-filled nodules. The left occipital pole was congested and hæmorrhagic. Recent ante-mortem thrombus was present in the superior longitudinal and left lateral sinuses. Other organs showed no obvious abnormality.

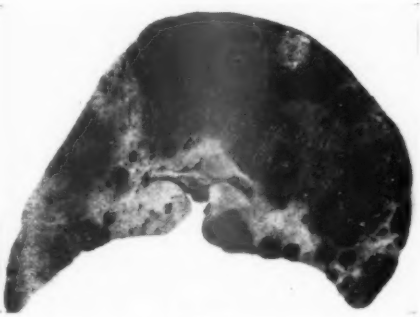

FIG. 2.

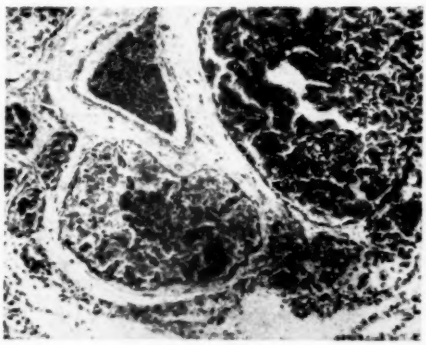

FIG. 3.—×79.

*Histology.*—A cavernous architecture is characteristic of the nodules in all the sites (Fig. 3). The tumour is formed of vascular spaces, many filled with blood, lined by endothelial cells which are flattened where the lining is one cell thick, but in many areas the cells are proliferating into the vascular spaces. Here they form rounded masses of cells of a more ovoid or polygonal shape. Mitoses are frequent.

In addition, and especially in parts of the mass near the apex of the left kidney, there are areas which show a more cellular pattern with finer vascular spaces, lined and separated by proliferating tumour cells (Fig. 4). Each nodule shows no surrounding fibrosis and infiltration outwards by the tumour cells is not a feature, but extensions of the vascular spaces insinuate between the constituent elements of the adjacent host parenchyma in the liver and kidneys. Tumour emboli in small vessels are seen in the sections of the lung (Fig. 5): the pathological appearances explain the radiological miliary mottling.

Hæmopoiesis is nowhere recognised: necrosis is present principally in the mass in association with the left kidney. This mass also shows calcification and fibrosis.

*Comment.*—This case was clinically remarkable for three reasons. First because radiologically the condition very closely imitated miliary tuberculosis. Secondly, when the

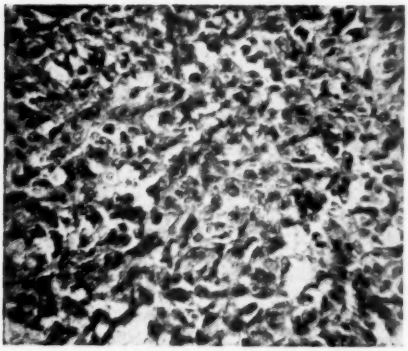

FIG. 4.—×198.

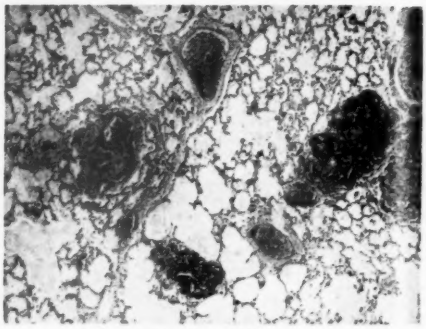

FIG. 5.—×30.

diagnosis of miliary tuberculosis became untenable, the calcification in the region of the adrenal suggested the probability of a neuroblastoma with secondary deposits elsewhere. Finally, histological evidence failed to confirm the second clinical diagnosis and replaced it with the diagnosis of a very rare condition.

The histological appearances demonstrated the vasoformative nature of this tumour whose proliferating cells are those lining the vascular spaces. It is therefore best called "hæmangio-endothelioma." Stout (1943) discussed this group of tumours. They are unusual and in the viscera have been most commonly described in the liver, especially in infants (Crocker and Cleland, 1957; Edmundson, 1956; Vidabaek, 1946) and may be found in the spleen (De Navasquez, 1936; Wright, 1949).

The present tumour is malignant and there is in addition evidence of terminal dissemination (Fig. 5). Vascular tumours are frequently multifocal and such a multiple origin is not excluded in this case. However, the appearance of the lesion in the region of the left adrenal suggests that it is of longer duration than those elsewhere. It is of interest that Menon and Annamalai (1934) described a hæmangioblastoma of the adrenal gland, and that in the case of a 4-months-old infant with a malignant hæmangioma of the lung (Wollstein, 1931) the adrenal was the site of a similar tumour.

**Neonatal Thrombocytopenic Purpura with Hæmangiomata.**—JEAN M. SMELLIE, M.A., B.M., M.R.C.P., D.C.H. (for B. E. SCHLESINGER, O.B.E., M.D., F.R.C.P.)

*History.*—A male infant admitted to University College Hospital Premature Baby Unit, aged 10 hours, following a normal delivery at home at 38 weeks.

Birth weight 4 lb. 4 oz. "Rash" noted at birth.

Mother aged 36, para–3. Normal pregnancy, except for pyelitis at 18 weeks and an I.V.P. at 20 weeks. No treatment given. No purpura during or before pregnancy. Spleen not palpable one week post partum.

*On examination aged 10 hours.*—Profuse purpuric rash varying in size from petechiæ to 1 cm. diameter, distributed over face > trunk > limbs. Few petechiæ in mouth. Spleen tip palpable. Liver 1 fingerbreadth. (*See* Fig. 1.)

*Investigations.—Infant aged 10 hours:* Hb 110%; platelets 23,000; bleeding time > 13 min.; clotting time normal. W.B.C. 16,500 (polys. 80%, lymphos. 15%, monos. 4%, eosinos. 1%); normoblasts 36/100 W.B.C. Direct Coombs' negative. W.R. and Kahn negative.

*Aged 6 days:* Marrow (R. tibial aspiration): No megakaryocytes seen in four smears, otherwise morphologically normal (Dr. E. M. Graves).

*Mother 7th day post partum:* Hb 98%; platelets 300,000. W.R. negative. Rhesus positive. Direct Coombs' negative.

No platelet antibody estimations were made in mother or infant.

FIG. 1.—R. H., aged 6 days, showing purpura.

*Treatment and progress* (*see* Fig. 2).—Started at twelve hours with ACTH gel 10 units and continued daily for six days. Platelets remained low, hæmoglobin level fell and fresh petechiæ developed.

*6th day:* Changed to oral cortisone for two weeks, 20 mg. daily steadily reduced to 5 mg.

A transfusion of 70 ml. packed stored cells was required for anæmia on the ninth day of treatment. Platelets rose to normal levels (190,000 at three weeks). During a three-week period without treatment the hæmoglobin fell without obvious purpura or bleeding but rose after cortisone was re-commenced. Dosage was reduced gradually from 20 mg. to 2·5 mg. daily and this maintenance dose was continued until seven months. Ferrous gluconate 100 mg. b.d. was given until fifteen months.

*Subsequent progress.*—Spleen palpable until 7 months. Platelets normal from 3 weeks. Marrow smears from iliac crest aspiration showed:

2 weeks —No megakaryocytes.

While on cortisone (2½ weeks to 5 months):

2½ weeks —1 atypical megakaryocyte.
2 months } Very occasional mature
5 months } megakaryocytes.
11 months —No megakaryocytes.

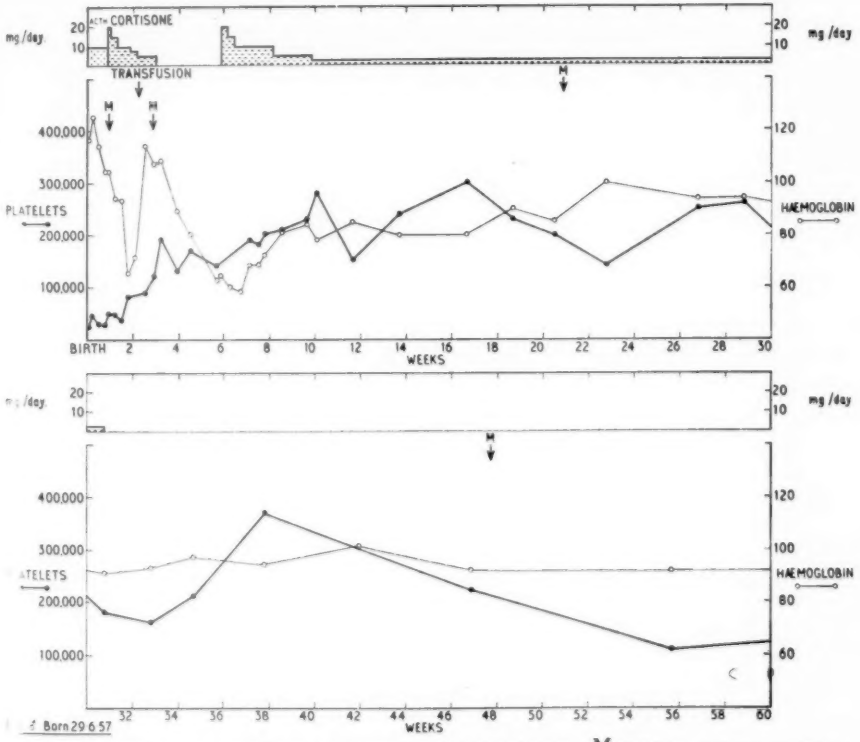

FIG. 2.—Platelets/c.mm. and Hb % (14·8 grams = 100% Haldane). M ↓ indicates marrow puncture.

Hæmangiomata of the raised capillary or strawberry nævus type first noted at five to six weeks. Distributed mainly right side of body, right upper arm, chest, thigh, knee and lower eyelid; the last was treated with carbon dioxide snow (Dr. P. J. Hare). Fresh hæmangiomata developed until eleven months when he had a total of ten.

Pertussis 16 months. Otitis media 11, 13 and 14 months. Milestones: normal physical and mental development.

*Comment.*—The main features of interest are: the occurrence of thrombocytopenia in an infant where the mother was normal; the persistent deficiency of megakaryocytes in marrow smears; and the association of hæmangiomata with thrombocytopenia.

Considering the ætiology and mechanism of the purpura, Stefanini and Damashek (1955), Robson and Walker (1951) and others have divided cases into those born to mothers with idiopathic or secondary thrombocytopenic purpura and those born to normal mothers.

Where the mother had idiopathic thrombocytopenic purpura with or without a previous splenectomy, platelet antibodies have been demonstrated in most cases in which these have been investigated (Harrington *et al.*, 1953).

Where the mother was normal, the possible mechanisms were:

(1) Congenital hypoplasia of marrow of the Fanconi type.

(2) Congenital aplasia of megakaryocytes.

(3) Mother-baby anti-platelet antibody mechanism, analogous to hæmolytic disease.

In this case, the marrow showed no general hypoplasia or evidence of leukæmia.

In the true amegakaryocytic types as described by Bell *et al.* (1956), Emery *et al.* (1957), and Greenwald and Sherman (1929) the outcome was fatal, there being no response to cortisone or splenectomy where this was tried and there were other congenital malformations.

Lastly there was the possibility of the production of anti-platelet iso-antibodies in the mother (Schoen *et al.*, 1956; Harrington *et al.*, 1953; Tullis, 1956).

Against this was the absence of megakaryocytes in the marrow. A normal or increased number of megakaryocytes would be expected as this occurs in idiopathic thrombocytopenic purpura in children or adults.

In the literature, however, there are few marrow studies reported in patients in whom platelet antibodies have been demonstrated and the reverse is also the case; where the marrow has been examined, antibodies have not been estimated. However, in at least two reported cases of neonatal purpura occurring in infants of mothers with idiopathic thrombocytopenic purpura when this is presumed, but not proved, to be an immune mechanism, the marrow has been found deficient in megakaryocytes at post-mortem (Whitney and Barritt, 1942; Finn, 1944).

In favour we have the brief period of purpura (which might have been self-limited as is the common course if untreated) and the apparent response to cortisone in the child of a multiparous mother. Although megakaryocytes were still sparse or absent in marrow smears at 11 months the circulating platelets remained normal in number from 3 weeks and the megakaryocytes may have been producing them, possibly in the liver.

It was unfortunate that we were unable to estimate the anti-platelet antibodies at the time of admission, as this alone would provide the answer.

Lastly, the association of thrombocytopenia with hæmangiomata may be incidental, but is well documented. In most of the reported cases, hæmangiomata have preceded the purpura and no improvement in thrombocytopenia has occurred from splenectomy or cortisone until the hæmangiomata have regressed spontaneously or following therapy (Huysinga and Minder, 1957; Silver *et al.*, 1948; Meeks *et al.*, 1955).

**Thyrotoxicosis in a Mongol.**—J. H. DIGGLE, M.B., M.R.C.P., and R. S. WEETCH, M.B., M.R.C.P. (for T. COLVER, M.D.).

J. A., female, born 30.4.49. First seen at 1 month old with the usual signs of mongolism. The heart is normal. She first walked at 3½ years and showed marked mental retardation.

*History.*—At 6 years of age she began to lose weight and over the following seven months she developed exophthalmos and thyroid enlargement and became very excitable and was restless at night. There was little sweating but she always felt hot to the touch. Later there was polyuria and diarrhœa.

*On examination.*—Height 44¼ in. (within normal range; female mongols are often 4 to 8 in. short of the lowest 5 percentile). Weight 33 lb. (well below the 5 percentile).

The thyroid was soft and diffusely enlarged with a systolic thrill over it. Pronounced proptosis present with lid retraction, more marked in the left eye than the right (Fig. 1). Heart-rate 150 per min. Sleeping pulse 125 per min. average. Blood pressure 130/60. The heart was overacting and slightly enlarged on X-ray. No cardiac murmur was heard. No tremor of the hands was seen but there were jerky movements like chorea. Temperamentally she was sensitive and emotionally labile. Much more animated than most mongols: hyperkinetic at times.

FIG. 1.

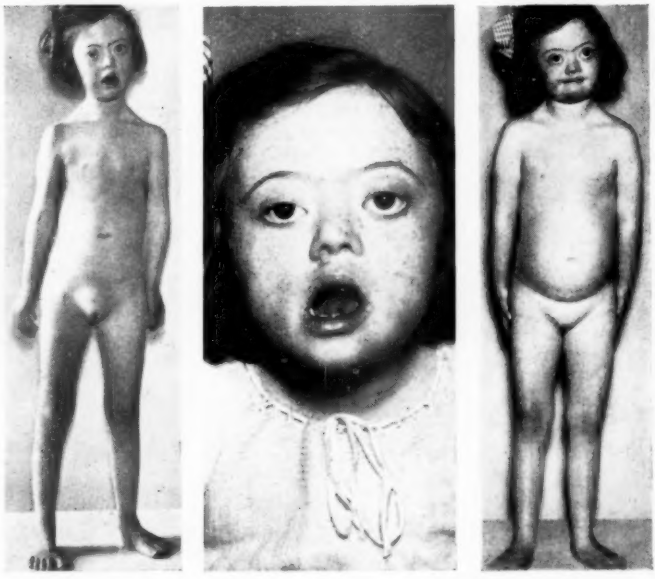

FIG. 2.

*Investigations.*—Bone age probably 10 years, i.e. all carpal centres were present, including the pisiform. X-ray of skull showed a normal pituitary fossa.

Serum cholesterol 130 mg. %. Total serum lipoids 275 mg. %. B.M.R. was not attempted on account of her low I.Q.

$$\text{Ratio of } \frac{\text{Creatine}}{\text{Total creatine + creatinine}} \text{ was } 15{\cdot}6\% \text{ (normal).}$$

Radio-active iodine studies: 5$\mu$c. of $^{131}$I given

(1) Thyroid gland uptake:
- After one hour 56% of dose given.
- After four hours 84% of dose given.
- After forty-eight hours 74% of dose given.

(2) Blood concentration of $^{131}$I: The conversion ratio =

$$\frac{\text{Protein-bound iodine} \times 100}{\text{Total plasma activity}} = 83{\cdot}7\%.$$

In spite of a possible total error of 13% due to technical factors these figures show unequivocal evidence of well-marked thyrotoxicosis.

A therapeutic trial with Lugol's iodine subsequently produced a fall of 20 per min. in the average pulse rate and during four weeks on potassium iodide the patient gained 6½ lb. and became quiet and much less active. The pulse pressure fell from 70 mm. to 35 mm.Hg.

*Treatment.*—Carbimazole 15 mg. per day was given for four weeks, then the dose was gradually reduced to 7½ mg. per day. She lost all signs of hyperthyroidism and became slower, rather obese and much easier to manage at home. The exophthalmos has almost disappeared and the thyroid gland is now small and firm (Fig. 2).

Since the thyrotoxicosis has been controlled the 17-ketosteroid excretion has been estimated at 1·1 mg. in twenty-four hours, which is the upper limit of normal at this age. Ketogenic steroids were 5·0 mg. in twenty-four hours.

*Comment.*—Gilchrist (1946, *Brit. med. J.*, i, 237) described a female mongol aged 22 with thyrotoxicosis and McGirr and Murray (1956, *J. clin. Endocrin.*, **16**, 1) reported a case in a female mongol of 23.

Thyrotoxicosis is very uncommon in young children and it is the great rarity of its combination with mongolism which prompts us to present this paper.

We wish to acknowledge the help received from Dr. Harold Miller (Physicist) who carried out the radio-iodine measurements.

**Symptomless Hypoplasia of One Thenar Eminence in Childhood—The Presenting Feature of a Bizarre Developmental Syndrome** (Two Cases).—TREVOR P. MANN, M.D.

*Case I.*—P. H., born 3.2.49. (Shown November 23, 1956, aged 7½ years.)

*History.*—Referred to hospital with "wasting" right thenar eminence, first observed in infancy, and asymmetrical head posture simulating torticollis. A healthy child. Right-handed. No paræsthesiæ or other subjective symptoms affecting hands.

*On examination.*—Position of shoulders asymmetrical—right lower than left. Head slightly deviated towards right shoulder (Fig. 1). Upper dorsal kyphosis. Marked "wasting" right thenar eminence—scooped out appearance (Fig. 2). Interossei normal.

FIG. 1 (*Case I*).—Head deviated to right. Drooping of right shoulder.

FIG. 2 (*Case I*).—Hypoplasia of right thenar eminence.

No muscle tenderness. Sensation hands intact. C.N.S. normal. Slight weakness of opposition and thumb abduction movements right hand. Right thumb and nail definitely smaller than left thumb and its nail. Brachial pulses equally palpable; brachial blood pressure equal on two sides. Absent right radial pulse—not palpable after immersion in a hot bath. Right ulnar pulse palpable. Left radial and ulnar pulses normally palpable.

*X-ray examination* (Dr. J. Rubin).—Cervical spine normal. Transverse processes C.V.7 prominent but not abnormally so. No cervical ribs. Dorsal spine: no evidence of scoliosis. Hands: Delayed development of right lateral carpal bones. No ossification is yet evident in right scaphoid and its centre usually appears by 5 years (usual limits 3 to 8 years). The trapezium is much smaller on the right side. There is a little atrophy of the first metacarpal bone, its shaft being definitely thinner and its cortex slightly thicker than the corresponding left bone. Its proximal epiphysis is slightly smaller and rounder than the left epiphysis which is more oval in shape. The thumb phalanges are also very slightly smaller on the right (Fig. 3).

FIG. 3 (*Case I*).—Delayed development of right lateral carpal bones. Narrowing of shaft of first right metacarpal bone.

FIG. 4 (*Case II*).—Delayed development of right lateral carpal bones. Narrowing of shaft of first right metacarpal bone.

*Case II.*—C. P., born 13.10.50. (Shown November 22, 1957.)

*History.*—December 1956 attended hospital with injury to right wrist following a fall. "Wasting" of right thenar eminence noted by the casualty doctor. This had not previously been observed by the parents. A perfectly healthy child. Left-handed. No paræsthesiæ affecting arms or other symptoms such as circulatory and temperature changes.

*On examination.*—Physical signs essentially the same as those given above for Case I and summarized below:

*X-ray examination* (Dr. J. Rubin).—Cervical spine normal. No cervical ribs. There is a pseudo-arthrosis of the first and second right ribs. There is a definite difference in the development of the hands and wrists—the right being retarded in comparison with the left (Fig. 4). Thus there is an obvious difference between the two scaphoids, the maturation on the right side lagging about one year behind the left. Also the right trapezium and trapezoid

similarly show retarded development. The distal epiphysis of the right ulna consists of two small ossific centres whereas a well-defined bony centre is evident on the left. The first right metacarpal shaft is thinner than the left and its cortex thicker on the medial aspect. Its proximal epiphysis is slightly smaller and more rounded than the corresponding left epiphysis which is more oval in shape. Comparison of thumb phalanges on the two sides shows the right ones to be slightly smaller.

The syndrome exhibited by these 2 children consists of the following components:

(1) Hypoplasia of one thenar eminence and, to a lesser degree, of the related thumb.

(2) Absence of the radial pulse on the affected side.

(3) Drooping of the shoulder on the abnormal side.

(4) X-ray changes in the thumb bones and wrist of the abnormal limb which in essence are: (*a*) Delayed development of the lateral carpus, retardation being especially conspicuous in the scaphoid bone. (*b*) Narrowing of the shaft of the affected first metacarpal bone, the proximal epiphysis of the latter being smaller and more rounded in shape. (*c*) Hypoplasia of the thumb phalanges.

Hanley and Conlon (1957, *J. Bone Jt. Surg.*, **39B,** 458) have described a syndrome in two adults resembling the one reported here. Their Case 1, in particular, appears to be suffering from a very similar disturbance. It is difficult to assess their second case as the clinical account is incomplete. The affection was bilateral in these adults and in both there was an associated proximal bony abnormality as in Case II here (a large cervical rib in one and a spina bifida of the first thoracic vertebra in the other).

This syndrome, presumably congenital in origin, must be considered in the differential diagnosis of "wasting" of the intrinsic thumb muscles in children and adults. It does not appear possible to relate, in embryological terms, the various anatomically associated tissue defects.

I am indebted to Dr. Eva Frommer for drawing my attention to Case II.

**Tropical Eosinophilia.**—C. W. KESSON, M.D.

M. C., male, aged 11 years. Cingalese, born in Ceylon but moved to Singapore at 1 year of age and to the U.K. in May 1956.

*Family history.*—Parents well with normal white blood counts and negative W.R. and Kahn reactions. Maternal great-uncle treated for tropical eosinophilia in Singapore 1953. Another maternal great-uncle and a great-grandmother suffered from asthma.

*Previous illnesses.*—Treated for roundworms 1949. Tonsils and adenoids removed 1954.

*Present illness.*—Fever and purulent nasal discharge began in December 1956, and progressed to cough, wheeziness and severe dyspnœa. The illness lasted two weeks but some cough persisted and he remained short of breath on exertion. Exacerbations occurred every four to six weeks and in April 1957 he was referred to Victoria Hospital for Children, two weeks after an episode. At that time there was no evidence of respiratory infection. Spleen palpable, W.B.C. 20,000, 61% eosinophils.

He was admitted later in a typical asthmatic attack. His temperature was 99° F. He had a mild upper respiratory tract infection. There was marked bronchospasm and generalized expiratory rhonchi. The edge of the spleen was 1 in. below the costal margin.

*Progress.*—The asthmatic attack subsided with aminophylline and phenobarbitone though a cough with some coarse scattered rhonchi persisted. Repeated stool examination failed to reveal ascaris ova but a course of hexylresorcinol was given. No worms were passed. On 10.6.57 he developed a temperature of 101° F. with faucial infection and an asthmatic attack. Next day a week's course of oral Stovarsol was instituted and injections of penicillin for the streptococcal throat infection. The temperature remained raised till 22.6.57 when his general condition began to improve. He was discharged well on 2.7.57. The spleen remained enlarged. W.B.C. 18,000, 43% eosinophil cells.

He has remained well and free of asthma. W.B.C. now 8,800 with 10% eosinophils.

*Investigations.*—Chest X-ray: increased vascularity of lung fields. Mantoux 1 : 1,000 negative. Sputum: pus cells predominated. Fæces and urine: N.A.D. Blood: protein 7·2 g./100 ml. Marked increase in $\gamma$ globulin. W.R. and Kahn positive on 24.5.57 and 31.5.57. Treponemal W.R., standard W.R., and Price's precipitation reaction negative on 13.6.57. W.R. and Kahn negative on 24.9.57. Films showed no malaria or microfilaria.

Skin tests: pollens, Casoni, histoplasmin, coccidiosis negative. Filaria positive.

The following cases were also shown:

**Cushing's Syndrome.**—Dr. E. GOLDBLATT (for Dr. A. P. NORMAN).

**Aldosteronism in Infancy.**—Dr. J. W. PLATT (for Dr. B. E. SCHLESINGER).

**Hepatomegaly ? Cause. Failure to Thrive.**—Dr. LESLIE SCOTT.

**Meningococcal Septicæmia and Early Meningitis.**—Dr. M. PEARD (for Dr. URSULA JAMES).

[*January* 14, 1958]

## DISCUSSION ON THE LEGAL ASPECTS OF SUICIDAL ACTS

**Dr. Doris Odlum** (Bournemouth):

Suicide is a felony. It is a common law offence and regarded as a form of homicide. The origins of this law are lost in antiquity, but there are records relating to it dating from mediæval times. The original penalties were burial at a cross roads with a stake through the heart and forfeiture of goods to the Crown. As the result of pressure of public opinion this form of burial was discontinued from 1824 but suicides had to be buried between 9 and 12 at night without any ceremonial in unconsecrated ground. This was not repealed until the 1880s. The confiscation of goods was discontinued from 1870. In spite, however, of the removal of all sanctions, suicide still remains a felony in law. This has given rise to the custom of coroners giving a verdict that the balance of mind was disturbed in a large number of cases. From the point of view of the relatives and friends it is doubtful whether it is less distressing to have to face a verdict of felony or mental derangement. Attempted suicide, because it is an attempt to commit a felony, is itself an indictable offence and comes under the category of a misdemeanour. A conviction therefore carries the stigma of a criminal record. It is described in legal language as "unlawfully attempting to commit suicide against the peace of our sovereign lady, the Queen, her crown and dignity". Cases formerly had to be tried at quarter sessions or assizes. By the Magistrates' Acts of 1935 to 1951 they can now be tried before a Magistrate's court with the consent of the accused. The maximum penalty that a Magistrate's court can inflict is six months' imprisonment but if tried at Assizes or Quarter Sessions heavier penalties can be inflicted and a sentence of two years' imprisonment was recently given. (This, however, was reduced on appeal by Lord Justice Goddard to two months' imprisonment.) The criminal statistics for the years from 1946 to 1955 show that the total number of cases of attempted suicide known to the police were 44,956. Of these, 5,794 were brought before the courts and subjected to trial. 5,447 were found guilty and thus stigmatized as convicted criminals. 308 were sentenced to terms of imprisonment without option of a fine. The numbers of men sentenced to prison were slightly higher than those of women. Thus an average of over 13 people in a 100 were prosecuted and practically all were convicted. It is therefore obvious that the legal attitude to attempted suicide is still largely mediæval. It has been claimed that attempted suicides are only brought to court for their own protection, but evidence is available that this is by no means always the case.

In 1947 a joint committee of doctors and magistrates sponsored by the British Medical Association published a report entitled "Attempted Suicide, the need for an alteration in the Law". This report was endorsed by the medical members of the committee and accepted by the Council of the B.M.A., but at the time no further action was taken. In July 1956 the Representative Body of the British Medical Association passed a resolution deploring the fact that during recent years a considerable number of people had been imprisoned for attempting suicide and supporting the conclusion of the 1947 report that there was a strong case for amendment of the law so that attempted suicide would not be dealt with as a legal offence and suggesting that the committee should give further consideration to the matter and also to the treatment of attempted suicides, having regard to the fact that the majority were in need of psychiatric treatment. The joint committee have, during the past eighteen months, been considering the whole question. They have taken evidence from a number of consultants in general hospitals who have stated that they find no difficulty in dealing with

attempted suicides from the medical and social point of view without invoking legal intervention. The committee has considered the report of Dr. Epps on 100 women in prison on attempted suicide charges. It has also received oral evidence from Professor E. Stengel, Professor of Psychiatry at Sheffield University, and discussed his paper on "Society and Suicide". It has considered a report on the subject which has been accepted by the Council of the Medical Women's Federation which considered that the present law required amending. It has received information about the law and practice in other countries. With the exception of India and some of the American states there is no country which regards attempted suicide as an offence in law. It has received evidence from Austria, France and other countries where there is no legal intervention that they do not appear to find any difficulty in dealing with cases of attempted suicide. In Scotland attempted suicide is in the large majority of cases dealt with as a medical matter but in the very few cases where there are no relatives or friends available and where the individual is entirely unco-operative, it is dealt with as a breach of the peace in the interests of the person who has made the attempt and/or the community. No evidence has been found to support the claim that the fact that attempted suicide is a crime acts as a deterrent nor that the attempted suicide derives any benefit from being brought to trial, convicted, remanded as a convicted criminal to a prison hospital for investigation, or imprisoned. There is, on the contrary, much evidence that this greatly adds to the distress both of the person who has attempted suicide and of his family and friends. Cases where, after conviction, the attempted suicide is put on probation on condition that he accepts psychiatric treatment could be much better dealt with by the medical and social agencies available without the intervention of the law.

It would appear that in the large majority of cases there is no good reason for legal intervention at all. In the few who will not co-operate and who have no friends or relatives who are prepared to take care of them the difficulty could be met by making the breach of the peace procedure applicable in England and Wales to those who require care and protection for their own safety or in the interests of the community.

The question has been raised as to the position in regard to life assurance policies. Information has been obtained from the leading insurance companies to the effect that if a person has paid one year's premium the policy would be fully honoured in the case of suicide regardless of the coroner's verdict. No policy would be determined because the holder had attempted suicide. Therefore the legal position does not affect the insurance issue either way.

A criminal record, however, could prejudice the possibility of obtaining an emigration permit or of obtaining certain posts either in this country or overseas. The question has also been raised whether the doctor has a duty to report a case of attempted suicide to the police. Advice has been taken on this point and it would appear that there is no obligation on any citizen to report a misdemeanour. He would, however, have an obligation to report a case of accomplished suicide as this is a felony.

It would appear that the only possible reason for continuing to regard either suicide or attempted suicide as a criminal offence would be the concept that suicide is a form of murder and therefore should be punished from a retributive point of view or as a possible deterrent. It has already been pointed out that there is no evidence that it does in fact act as a deterrent. The concept of purely retributive punishment is no longer acceptable to the majority of the community who take a more humane and constructive attitude.

**Dr. P. Epps** (London):

I propose to leave the more theoretical and historical aspects of the relation between the law and suicidal acts, and to concentrate on the practical side of this problem. During the three years 1954–1956, I interviewed a consecutive series of 100 women admitted to Holloway Prison Hospital on charges of attempted suicide. Those women who had additional charges such as larceny, fraud, &c., were excluded from this series, except in two cases where the other charge was not pursued.

All the 100 women (except one, who appeared at Sessions) came from Magistrates' courts in London and in those counties from which Holloway draws its population, i.e. the Home Counties, East Anglia and the South and East of England. The women fell into three categories: firstly, 51 were sent by the courts under Section 26 of the C.J. Act of 1948, which means they are convicted of the charge, but are sent from court into prison for one to three weeks for a medical report and recommendation, with which they then return to court; although they have the advantage of this report and recommendation, they suffer the disadvantages of a convicted person while in prison. Secondly, 43 were admitted on remand with a request for a medical report in 31 cases. Thirdly, 6 were admitted already sentenced,

the sentences varying from three to nine months' imprisonment. We can conclude that the courts are usually ready to seek medical advice, since in 82 of the 100 cases a medical report was requested from prison, and in some of the remaining 18 cases it may have been available from some other medical source.

Turning now to events occurring between the suicidal attempt and the first court appearance, the large majority, 75, had been treated in general hospitals. Of this 75, 30 had been kept in hospital for only a few hours for first-aid treatment, 23 spent up to three days, 15 from three to seven days, and 7 from one to two weeks. The 53 who spent three days or less in general hospitals were probably seen only by casualty officers or junior doctors, and one wonders if they were assessed on their physical rather than their psychiatric state. The 22 who were retained longer than three days and up to two weeks may have had the advantage of a psychiatrist's opinion and recommendation to the court. These general hospitals appeared, on the whole, to have been large ones, and in London 16 of the patients came from 8 teaching hospitals. Of the remaining 25, 15 were under psychiatric supervision, 9 in observation wards and 6 in mental hospitals, one of the latter being sent there by the court for a medical report. The remaining 10 went directly to a police station and thence to court, apparently because of the trivial harm sustained by the patient in the suicidal attempt.

The majority of these women, 64, had had no previous acquaintance with courts or prisons and a further 6 had only been acquainted through an earlier charge of attempted suicide. The remaining minority of 30 had previous convictions for larceny, drunkenness, &c. A total of 11 had previously been charged with attempting suicide, and of these 7 had been put on probation (2 on two occasions), 2 sentenced to imprisonment, 1 certified insane and 1 given an absolute discharge. Since these 11 reappeared on the same charge, it is doubtful whether these previous convictions had had any deterrent effect, and this opinion is reinforced by the fact that 42 of the 100 admitted that they knew that court proceedings could follow their suicidal acts.

The usual medical and social details were noted in taking each woman's history, and the group as a whole was not very different from those other groups collected in observation wards, such as Professor Stengel's group (1952) and Dr. Batchelor's group in Edinburgh Royal Infirmary (Batchelor and Napier, 1954). Ages varied from 17 to 81, 75% being under 40 years of age. Social isolation and unhappy homes were prominent; 44 were married, but of these 27 were separated or divorced, 10 claimed to be unhappily married and 2 had husbands in prison. Only 5 said their marriages were happy, and of these 2 were epileptic, and 2 psychotic; 8 were widowed and of the 48 single women, 12 were cohabiting or in unsatisfactory, involved situations.

Physically the group was a healthy one; only 2 women, one with asthma and 1 with tuberculosis, had any physical disability. But 49 gave a history of past mental illness, 42 having been in mental hospitals, 20 more than once. 10 had been certified, 27 had been voluntary patients, and 5 both certified and voluntary. 4 had had psychiatric out-patient treatment, 3 had been treated by their own doctors, and 2 had had leucotomy. 44 admitted to previous attempts at suicide; the rest seem to have been charged on their first attempt, which is not in line with the commonly held belief that the police never charge anyone on their first attempt.

This high incidence of past mental illness suggests that this is a mentally ill group, and this is confirmed by diagnosis. Of the 100 women, 49 were classed as neurotic, 19 as psychotic, 16 as psychopathic, 11 as epileptic and 5 as borderline or mental defectives. There were 24 chronic alcoholics in the group, 16 of whom attempted suicide after drinking. Of these 24 alcoholics, 10 were diagnosed as neurotic, 8 as psychopathic, 4 as psychotic, 1 as epileptic and 1 as a borderline defective.

Alcoholism was rather commoner in this prison group than in those two groups previously mentioned, and this may explain to some degree the short period for which some of these patients were retained in general hospitals after the attempt. Some patients can be a disturbing influence in a ward; this would mainly apply to alcoholics and some psychopaths, and in such cases a charge such as breach of the peace or drunkenness would meet the case. The abolition of "attempted suicide" as a charge would avoid the admission to prison of mentally ill patients, to whom such an experience may be an additional cause of depression and to whose relatives it can be a source of distress.

In the recommendations sent to court, 12 were recommended for certification, 11 as insane and 1 as mentally defective; 38 were referred for treatment as voluntary patients in mental hospitals, and the court included a probation order for 21 of them. 27 were placed on probation, of whom 21 were recommended for treatment at a psychiatric out-patient clinic. Half the group therefore was thought to be in need of in-patient treatment in mental hospitals, and a further 21 of out-patient psychiatric treatment. 7 were sent to a hostel or convent,

5 of them on probation. The total put on probation by the court was 53, more than half. 6 were discharged by the court.

The remaining 10 were sentenced to imprisonment, varying from two to nine months. 3 appealed, all successfully, against their sentences, 2 being placed on probation and the third being treated as a voluntary patient. 1 was certified as an alcoholic psychotic during her sentence and 6 completed their sentences. It is difficult to see why these particular 10 were sentenced; 6 came from courts in the provinces, and 4 from London; 3 had had numerous previous convictions, 4 had had none, while the 3 who appealed had each had 1 previous conviction. 4 were psychopaths, 3 neurotics, 1 of whom was alcoholic, 1 was epileptic and 1 a borderline mental defective. No definite sentencing policy is discernible, but possibly it is too small a number to allow conclusions to be drawn.

With reference to charges of attempted suicide admitted to men's prisons, Sir Norwood East (1913) published a paper on 1,000 cases admitted to Brixton Prison in the previous three and three-quarter years. This suggests that there was an approximate yearly intake of some 250 men on this charge. Dr. J. C. McI. Matheson, recently Principal Medical Officer at Brixton Prison, tells me that in 1955, 44 men were admitted on this charge, showing a considerable decrease in comparison with Sir Norwood East's figure, for which the increase in psychiatric services in the country would seem to be one of the main reasons.

The annual criminal statistics for England and Wales show that some 4,000 to 5,000 attempted suicides are known to the police each year, the figure having a tendency to rise over the past ten years, so that it stood at 5,220 in 1955. Of these, the police usually charge about 1 in 8, so that proceedings were taken against some 600 (twice as many men as women) in Magistrate's courts in that year. It is generally thought that the main factor that accounts for a charge being made is the absence of any relative who will hold himself responsible for the safety of the person concerned in the attempt and the consequent fear of further suicidal attempts.

It would appear that this solution of the problem, arrived at between police and relatives, leaves out of the picture the psychiatric assessment and treatment, opportunities for which have increased so much with the growth of the psychiatric services both in mental and general hospitals, for in-patients and out-patients, in recent years. Not only is there increased facility for psychiatric treatment, but also there are more social agencies than in former years, particulars of which are better known to psychiatric and other social workers than to the police.

To return to the attempted suicides proceeded against in 1955, I should like to mention two of the methods for dealing with them, namely, probation and imprisonment. Probation appeared to be the most popular means of dealing with the prisoner, as it was in the case of the 100 women previously described, and accounted for 358, or more than half. Excellent though the supervision given by Probation Officers is, these patients mostly need psychiatric treatment and time and effort would probably be saved if the supervision was left to social workers in the mental health services.

In contrast to the large number put on probation, a prison sentence was given to 44, the sentences varying from two weeks to six months. It is not revealed how many appealed against their sentence, but all those who appealed among the women mentioned earlier were successful. This suggests that there is some doubt within the legal profession as to whether a prison sentence is suitable for this offence, and may even indicate an alignment of opinion between both lawyers and doctors that the man or woman who attempts suicide should not be regarded as a criminal.

Finally, to summarize these points already touched upon, which would appear important and perhaps controversial:

(1) The majority appear to spend so short a time in general hospitals between the suicidal act and the court appearance that it is doubtful if they have had anything more than an assessment of their physical state.

(2) The large majority have had no previous acquaintance with courts or prisons, and even though they remain in the prison hospital and not in the prison, such an experience is inadvisable in those already mentally ill.

(3) There is no evidence that any deterrent purpose is served by charging these patients.

(4) The use of probation for the majority of these cases shows a lack of economy in the use of the available social services.

(5) The growth of psychiatric services in this country over recent years defeats the argument that prison should be used as a place of safety for the potential suicide. Though suicide may generally be regarded as an undesirable or even as an anti-social act, we in this country are

in the minority in regarding it as a criminal act. Moreover, we are illogical in that those who fail in the attempt are treated as criminal, while those who succeed are usually found at the coroner's inquest to have been unbalanced in mind.

I am indebted to the Prison Commissioners for permission to give the details of the 100 women seen in prison, but any views expressed are my own and not necessarily those of the Prison Commissioners.

**Dr. I. R. C. Batchelor** (Liff, Dundee):

An attempt to commit suicide is not *per se* an offence in Scotland. The individual may be hurried to hospital by the police and no legal action taken; or he may be charged with a breach of the peace: it is exceptional for him to be brought before a court. There is no hard-and-fast procedure in Scotland, the practice varying in different parts of the country. The percentage of cases of attempted suicide reported to the police in Scotland is not accurately known; in one city hospital records suggest that perhaps one-half of the cases are not so reported.

When the suicidal individual is charged with a breach of the peace, most often the suicidal attempt has been made in public and proceedings are taken on the grounds that the attempt has been carried out in circumstances which tend to alarm the lieges and constitute a breach of public order. For example, a shop assistant, aged 20, was charged because she "did attempt to commit suicide by jumping from a balcony on the first flat of a tenement, to the ground below, a distance of approximately 20 feet and did thus commit a Breach of the Peace". Rarely, when the suicidal attempt has been made in the individual's home, if the police have been informed by neighbours or relatives, a charge of breach of the peace may be brought: but if it did come to court, one supposes that a charge of breach of the peace, originating in such private circumstances, would be difficult to sustain.

Though these charges are made, the cases practically never come to court. The suicidal individual is taken to a general hospital by ambulance for treatment, and a "detention slip" is forwarded to the superintendent of the hospital from the local police station. This "detention slip" informs the hospital superintendent that his patient is a prisoner charged with breach of the peace and directs him to inform the police authorities the date and hour on which it is proposed to discharge the prisoner, in order that arrangements may be made for taking him into custody. The accused may be interviewed in hospital by two detective-constables, in plain clothes, cautioned and charged with the offence as libelled. The police interrogate witnesses and relatives and report to the City Prosecutor the circumstances of the case, the events which had preceded the suicidal attempt, the apparent causes of it, the individual's mental state (if known) and his or her response to the charge. In this report it is usually also stated that the individual has been or will be examined by a psychiatrist and his mental treatment undertaken. That is as far as legal action goes. The Prosecutor informs the police that he does not intend to take further proceedings, the charge is abandoned, the "detention slip" is cancelled, and the case rests in medical hands. If the hospital doctors state that the suicidal individual is unfit to be interviewed and charged, the police readily accept this advice, and the police themselves may decide on seeing the person that he or she is too unwell to be cautioned and charged. In the case of young persons particularly, the police may offer help from a court social worker or probation officer.

This legal practice is, from the psychiatrist's point of view (to state a personal opinion), open to criticism but not to severe criticism. Although the interview of the patient in hospital by the police is brief, it does aggravate in many cases the patient's distress of mind: one must add that an instance cannot be recalled when it was seriously prejudicial or seemed to have lasting ill-effects. The police officers are helpful, sympathetic and considerate in their attitudes, but from a medical point of view their visits are an intrusion, and tend to delay healing processes. Furthermore, to bring a charge when there is little or no intention of proceeding with it, seems sterile. Sometimes a suicidal individual will want to leave hospital as soon as he has regained consciousness or had his wounds dressed, and it has been serviceable in such circumstances to be able to point out that a "detention slip" has been issued by the police and that he must wait. But one can manage without this curb.

In one Scottish city all this is the usual practice, when a case of attempted suicide is reported to the police. In another city, when it is, so far as the police know, a case of a first attempt at suicide, the individual is given a "caution" regarding what he has done, but he is not charged. In a third city, the police neither caution nor make a charge, except in the rare

cases where there is a public commotion: they simply bring the individual who has attempted suicide to one of the general hospitals and leave him in medical hands. The attempted suicide is thus treated by the police like anyone else who has suffered an accident or injury and requires medical treatment: they consider him a sick person and take welfare action accordingly. They experience apparently no difficulties due to the individual's non co-operation: and they do not fear being charged with assault. Why should they, what court would listen sympathetically to such an accusation? The police intervene, and so do we all, with the instinct of helping a fellow-man or woman.

There is a small number of people who make repeated and even numerous suicidal attempts, most often temperamentally unstable people of psychopathic or epileptic constitution (Batchelor, 1954). These repeated attempts may constitute a social problem, and certification with admission to a mental hospital is not always possible. In such cases the police may more or less be provoked into bringing and taking to court a charge of breach of the peace; and this may be not unhelpful. The individual may then be placed on probation and may be directed to undergo psychiatric treatment.

In cases of attempted suicide where the individual tries to take his family with him, or other persons are involved, a charge is, of course, made and it goes to court. The survivor of a suicide pact may be charged with manslaughter or with non-capital murder.

In the bringing of a charge of breach of the peace in cases of attempted suicide, we see the relatively innocuous vestiges of a more serious legal attitude to suicide as an offence.[1] The procedure of treating the suicidal individual as a sick person is taking its place; it is already established in large areas of Scotland, and probably it will not be long before this is the common practice throughout Scotland. There is seldom an advantage, and usually definite disadvantages, in charging these people. It comes to the same in the end, the suicidal individual is placed in the hands of doctors in hospital, and it is clear that the public in Scotland, together with the police and the courts, now generally accept this as right and proper.

In 1956, in Scotland there were 397 deaths from suicide in a population of 5,145,000, a death-rate from suicide of 8 per 100,000. In England and Wales the death-rate from suicide at 12 per 100,000 stood 50% higher than that in Scotland. There has been no recent marked alteration in this differential suicide rate, and the number of attempted suicides (which out-number the suicides many times) bears probably a similar relationship to the suicides in both countries. These figures for suicides in the two countries do not on the face of it suggest that Scotland's more permissive legal attitude to suicide encourages these acts. In fact there is no evidence that legal sanctions have a significant effect in inhibiting suicide. Amongst some hundreds of people questioned about their fore-knowledge of the legal implications of their suicidal acts, most replied that the legal aspects of what they were about had not entered their minds. Their acts had been determined by morbid emotions which had gushed up to sweep away judgment and social restraints. Some of those who admitted that they did know that suicide was illegal, said understandably that they had not cared since they had expected to die. There was no evidence that these people had acted as they did because they knew that the legal penalties were negligible. Two-thirds said that they knew that they had acted against the law, a few gave themselves up to the police, but practically no one knew exactly what the law was or how it might affect them. Some thought that they would be put in prison, others that they would be sent to a mental institution. The knowledgeable exceptions were those who had been through it all before.

There is no doubt that many suicidal acts are aimed not purely at self-destruction but are socially orientated, and express either hostility to others or a call for help or both these impulses. Stengel (1952) has made a major contribution to the understanding of their sometimes equivocal nature. Our society should now be mature enough to tolerate the hostility of these acts and to respond constructively to the appeal for assistance, by giving unfettered the medical care and treatment which these sick people need. In Scotland this goal has been more nearly approached than in England.

**Dr. Irene M. H. MacAdam, J.P.** (Leeds):

From my early days in general practice and also from the outset as a magistrate I have been impressed by the unfairness of the legal machinery which may operate when a person tries to take his own life. Yet from the limited experience of fifteen years as a Justice of the Peace in Leeds it would appear that the problem of suicide is a small one compared with

other "crimes". As a member of a prison committee concerned with 700 men, one hears of or sees very few attempted suicides—perhaps the occasional case in the prison hospital—while in one particular six months I found only 6 such cases and these were all men on three weeks' remand. I feel that so long as it is possible for a visiting magistrate to find even one case in prison, then an attempt must be made to get this obsolete law changed.

The fact that the numbers throughout the country are not greater is primarily due to the very diverse and inconsistent way in which this law is administered in the cases that are discovered. It is a matter of chance whether such an unfortunate person makes the attempt in a town where the police seldom prosecute or in a place where the police seldom turn a blind eye on anything. A law which is so frequently evaded ought either to be ruled out altogether or at least amended so that it can be properly exercised. It is left to the discretion of an officer in the Chief Constable's department, whether a charge is brought or not.

The reasons usually given for bringing a charge are that it is a second attempt and that the offenders must be protected and treatment secured for them. There are measures well known to the medical profession for coping with the detention of these unfortunates and for their subsequent treatment but not all magistrates appreciate the facilities available. It is hoped that this type of mental illness will be provided for in any new legislation that may arise out of the recent Royal Commission Report on Mental Illness.

When cases are brought up with the idea of securing treatment, a probation order with the necessary "condition" is usually made. Such an order carries with it the sanction that the offender can be brought back to court if he does not fulfil the conditions and accept treatment. The work of probation officers in these difficult cases is of tremendous value but they are handicapped from the outset because the offender has already had to appear in court and perhaps been in prison. I would pay great tribute to the way the probation officers secure the best possible medical and psychiatric treatment for these people but surely it would be more fitting that a psychiatric social worker should be the one to make the enquiries and arrangements for treatment and then do the follow up case-work; at any rate someone who is not a servant of the court should do this work, to help to dissociate the idea from anything criminal. Despite the efficiency of the medical services when the cases become known to them, there may still be a few who escape the medical net or who refuse to be protected against themselves. When the emergency arises then the police must have the legal right to intervene or they would become liable to an action for unlawful arrest or detention. I submit that it would not be difficult for legislation to be evolved so that the police could take action in a manner similar to that used when a young person has to be taken into custody as "being in need of care and protection" or "being in moral danger". It should be possible for adults as well as children to be deemed "in need of care". If some form of legal sanction must be retained then let the person be brought before a Magistrate's court in this way; but personally I deplore the necessity of ever bringing these people into court and inflicting such an ordeal upon them. Should an attempted suicide cause some disturbance of the public peace a prosecution for a breach of the peace could be brought, as in Scotland. This would be tried summarily and would not give the person the stigma of a criminal record for an indictable offence, and so prejudice his future in regard to appointments, emigration, &c.

Many of those who attempt suicide do so for a histrionic purpose; they really have no genuine intention of ending their lives and are therefore not guilty of a "malicious attitude of mind". The onus of proving the charge that the attempt was genuine, is on the prosecution and if this cannot be done, there can be no conviction. In such cases it is particularly unfortunate that they have been charged.

Very few magistrates, or judges in higher courts, ever impose the severest penalties in their powers for this offence but it is surely a poor argument for the retention of these penalties that they need not be used! The court has a wide discretion and can apply any remedy it thinks suitable: absolute discharge, conditional discharge, probation with or without "conditions", or even a fine. Admittedly a properly informed court has ample facilities for very humane and sympathetic treatment.

The argument for retention of the criminal aspect in order to act as a deterrent has been disproved many times. If to attempt suicide is an offence not just against the person concerned but against the society in which he lives, then legally the present law is fulfilling one of its main purposes—to protect society—and it may do this by depriving the individual of his liberty. It is improbable that even the most conservative of legal luminaries will persist much longer in using methods of treatment for society's misfits which are quite contrary to all modern thought. If a moral sense as well as psychological stability is lacking then a court is certainly not the place to start rehabilitation. In the days before the medical profession could provide the knowledge and the means to deal with these cases, the courts had to exercise their power to enforce such treatment as was then available, but the law should now be brought into line with modern thought and attempted suicide should be considered as a medical and social problem and no longer as an indictable offence.

## DISCUSSION ON THE BREAST IN PREGNANCY AND LACTATION

**Dr. J. C. T. Sanctuary:**

*Notes on the Archæological and Anthropological Approach to the Subject of the Human Breast [Abstract]*

The breasts have held a vital place in the struggle for existence of the human race and it did not escape the observation of primitive man or those of early civilization how essential these organs were to its preservation and propagation.

The maternal breast as a symbol of the goddess of nature played its part among the ancients. Mother Nature herself was moreover regarded as so important that the number of her breasts was increased when portrayed both in drawing and sculpture as in the many-breasted Diana of Ephesus in the Naples Museum.

The reproductive features were further accentuated in portraiture and sculpture by the subject holding her genitals in one hand and a breast in the other. In mediæval and modern times this has been accepted as a covering of modesty but it was not always so, and a number of transitional forms have satisfied the archælogists that so far from being modest this posture was intended to accentuate the features to which the hands pointed.

Breast forms among primitive peoples are very typical of various races and tribes and local variations would also be obvious among members of the higher civilizations if they did not cover the breasts and artificially change their natural shape and position at will.

It is a fact that the more high-bosomed a woman may seem the more her ample bosoms would, if left alone, become dependent members. Primitive races indeed practise a simple form of bust control by tying a string round their pendulous breasts in order that these shall not interfere unduly with their daily activities.

To improve lactation is the object of all peoples by either rational or superstitious means. Studying only the latter we find many and varied substances used to stimulate or inhibit lactation.

There is a general tendency to encourage a grain and fish diet to produce milk while luxury foods are discouraged. Doubtless the fact that the male authorities presumably decide these matters in primitive areas has something to do with this arrangement which must be satisfying to them.

Among many sovereign remedies for poor lactation the following may be mentioned:

(1) Forcing the breasts together and tying them while turning the husband out to starve for seven days (Java).

(2) Stripping naked and waiting for breast irritation to start before suckling the infant (Maori).

(3) Prayers and libations, the suspension of a bag of mercury or an agate (milkstone) round the neck (various areas).

Among the ancients a good deal of sound advice was given. Said the ancient Israelites "When a woman suckles the work of her hands shall be lessened and her food increased."

The custom of keeping the husband aloof from the wife during suckling is widespread. In ancient Peru intercourse was forbidden during the time of lactation for fear of damage to the wife's health and milk production, but the husband was nevertheless encouraged to practise pederasty with his wife at this time. Other rules obeyed during lactation include

feeding the child from one breast only and never using the other (Sicily), forbidding the mother to spin for fear of giving the child vertigo (Transylvania), and feeding the child from the right breast first to avoid left-handedness (Wurtemburg), whilst in parts of Austria two nursing mothers must never drink together or one will drink away the other's milk.

In many places the onset of a menstrual period or a further pregnancy enforces a rule that suckling must immediately be stopped.

As to weaning, occasions recommended vary: the establishment of another pregnancy, a new, rising or full moon, but not a waning one. When the roses are in bloom and on Good Friday under a walnut tree (in Switzerland).

Positions in suckling vary in different areas. These are briefly as follows:

(1) European—The mother holding the child more or less horizontally.

(2) Western Asian and Eastern Europe—The mother hangs over the child which rests undisturbed.

(3) Eastern Asia (Japan)—The mother sits on the ground and the baby is rested on her knees.

(4) Hottentot—The infant is usually carried on the back and the mother throws the very long pendulous breasts which these races develop, over her shoulder and so suckles the child.

The period of time for which suckling continues varies considerably. On the whole, boys are breast fed for longer than girls and the racial extremes vary from Europeans and Hottentots, who suckle their young for less than twelve months, to Eskimos, who will continue up to the age of 15 years.

The treatment and prevention of breast infections have produced a number of interesting ideas. The Styrians poultice the breast with the heated urine of the patient and cool it with iron which has been put on ice. In Serbia the bride does not allow her husband to touch her breasts until after the wedding night. This is done to prevent pain while nursing. In Mecklenburg breasts and face are rubbed with placenta as a prophylactic measure.

There is a widespread and popular idea that it is fatal to the infant to apply a newborn baby to the breast very soon after birth.

Human milk has been used as a magical agency in the treatment of deafness, blepharitis, children's fevers, a badly healing umbilicus after shedding the cord, as an abortifacient, to expel a dead fœtus and as an aid to a normal delivery. Further uses have been in consumption, for the treatment of a rattlesnake bite and for the mutation of human beings to cranes or mushrooms.

In some parts of Africa if a woman suckles herself no husband dare refuse her request, whilst in New Guinea a girl swears by her swelling breasts as a man does by his beard.

The feeding of adults with human milk has been a common treatment of the enfeebled from Greece to Japan. A rather pleasing treatment of the hopeless lover is for him to suckle at his beloved's breast whereupon she becomes his "mother" and the passion is quelled.

Women have suckled animals among savage races in Australia, Polynesia and South America and Asiatic tribes.

In conclusion it is worthy of note that the Greek mythologists decided that Heracles was suckled by Hera as an adult while the sons of Zeus were not allowed to participate in divine worship until they had fed at Hera's breast.

**Dr. Mavis Gunther:**

The management of breast feeding is a technical subject in which rather remote theoretical knowledge is of direct practical value and it needs to be learnt by doctors and midwives for, with it, most of the troubles of lactation can be prevented. For instance, an analysis of the part played by instinct in the inception of feeding has clearly defined the objects of antenatal preparation. Both the mother's and the baby's parts can and commonly do fail for want of successful instinctive action and instinct here is found to have much in common with its other manifestations which have been so happily investigated by Lornz, Tinbergen and other workers.

The quality which ethologists observe is behaviour, an activity which is more than a reflex,

usually apparently purposive, appearing for the most part untaught. It is, of course, most easily studied in the newly-hatched or newborn because there is no confusion with other learnt behaviour but very much is also known, even of very elaborate patterns of instinctive behaviour in courtship, mating, nest-making and many other activities. From an immense amount of information, generalizations about instinct have been made which hold true throughout most of the animal kingdom and which are found to have an application in the early activity in the newborn human. Instinctive behaviour is evoked by specific patterns of stimuli, sign stimuli, which work within one sensory system calling out an innate release mechanism. One classical example of this is the attempt at feeding which a newly-hatched gull makes in response to seeing an article resembling an adult gull's bill. Here exact study can be made of the effectiveness of various cardboard substitutes by counting the number of attempts at feeding which a baby bird makes in unit time in response. A picture like a bill is most effective while, surprisingly, the addition of a cardboard representation of the parent bird's head makes no difference. This sign stimulus works entirely within the sense of vision. Other well-known but less exact examples of neonatal behaviour are the newly-hatched duckling's response to spoken duck language, the mechanism being auditory; and the behaviour of the geese described by Lorenz which became permanently attached in their affections to a human if they saw one instead of a goose in their first hours. This last example brings in other characteristics of instinctive behaviour: one is that it is often only evoked at one phase of life and another is that once some instinctive responses have been evoked, the animal's behaviour is altered from that time on.

There are two other characteristics which are relevant to the study of baby feeding: natural sign stimuli can sometimes be outdone by artifacts, by a super-normal stimulus. The well-known example of this phenomenon is the oyster-catcher who, if offered her own nest of eggs or a nest of similar ones made of wood and twice the size, will always sit on the wooden ones. Another phenomenon now recognized in instinctive behaviour is the elaboration of the primary instinctive behaviour by mimicry. Some birds will sing a simple song which is something like a mockery of the species' usual one if the bird is brought up isolated from its kind and the full song is only achieved after listening to others. Similarly some birds will only build token nests if reared without seeing a proper one.

In human behaviour instinct may operate or be lost and for many women the instinctive know-how of feeding has gone. Although a number of cliches can be produced to explain this, more help can be gained by considering a similar situation among chimpanzees. If the female is reared from an early age in captivity she is unable to feed her baby until she has been taught and it is customary now in zoos for a man keeper to stand by ready to teach the newly delivered chimpanzee. As far as I know, those chimpanzees who have known-how of their own accord came to captivity rather later than the others at an age comparable to 7 years in a human. It is likely, then, but there is no scientific proof, that the know-how of the mother's part in feeding which must have been necessary for the survival of each generation depends at least to some extent on mimicry, just as nest building can in a bird. It is quite certain that in chimpanzees, instinct fails the mother and it seems reasonable to expect modern Western mothers who, through present-day standards of modesty grow up without watching feeding from the breast, to have no knowledge of how to feed. It is unkind and decades out of date to count on their knowing.

Most mothers can learn their part rapidly if the baby's feeding behaviour is called into play. If a large number of babies are watched at their first feeds it is seen that many feed quite easily, some cannot and some achieve vigorous feeding only after one identifiable attempt. Successful feeding waits on the occasion when the pattern of tactile and pressure stimuli from the appropriate shape is received within the mouth. If comparison is made between a newborn baby's response to an empty bottle teat and his response to a teaspoonful of milk, the effectiveness of mere shape (the teat) is readily seen whereas a baby does not know what to do with the milk. A survey has been made of the conformity of the mother's breasts immediately after delivery with a device which measured how far the nipple and the tissues behind the areola would pull through a jaw-like gap if gently sucked in. This measured the protractility of the nipple in centimetres and the success or otherwise of feeding was almost entirely predictable from these figures. Where the length was more than a certain figure on this scale feeding was easily achieved, where it was intermediate success could only come if the baby were positioned to get maximum length. Where it was short the baby appeared to feel no urge to feed and stayed apathetically passive at the breast as if it were a premature baby. Where the baby received full oral stimulation, not only did he feed but from then on he would almost put himself on the breast within four or five experiences or sooner.

The physical shape of the breast is thought to be the normal sign stimulus which causes the baby not only to feed but to change in behaviour provided the baby receives it in the

first four days. Without it the baby may remain apathetic and even stay so for weeks. This fact that not only the baby's capacity to get on to the breast but also his eagerness depend on the conformity of the breast is of great practical importance. First, we are thought here to be dealing with realities as inescapable as other natural laws. If a baby does not feed because the breast will not pull far enough into his mouth, nagging will not replace the calling up of eagerness. And when the bottle teat is super-normal to the mother's breast the baby, without any choice, will respond to it and very soon develop a fixed preference comparable to other strong preferences in later life, rather like falling in love.

If, therefore, a mother is to feed her baby, the breasts at the end of pregnancy should offer the nipple as a knob for the baby to centre on and to draw to the back of the mouth, while the areola and the tissues deep to it should be softly yielding and protractile so that nipple and areola together, after passing the 2 cm. gap of the gums, go about 2½–3 cm., into the mouth. This yielding quality should be tested for early in pregnancy and aided by Woolwich shields where there is any doubt. The smaller the nipple the greater the need for compensating pliability in the retro-areolar tissues. The breast can only be assessed by touching, as the outward shape of the breast at rest is little guide. Dr. H. Waller, who invented the shield treatment, estimated that 40% of English primiparæ needed it.

The protractility of the nipple is more effective if the baby is correctly positioned with the lower jaw driving hard at the breast. There should be no gap and certainly no finger between. The ante-natal care and the after-delivery correct positioning bring the added reward that they save the woman from developing the commonest of the four types of sore nipples—the positional sore nipple.

The other main troubles of lactation can also be largely avoided. Engorgement of the breasts in the early puerperium is mostly prevented by giving mothers minute doses of stilbœstrol, 2 tablets of 0·25 mg. being taken an hour or two after delivery and one tablet a day later.

Two kinds of acute mastitis are recognized, the superficial and the intramammary. The superficial is a staphylococcal infection of the skin near or on the areola. It starts as a spot but instead of coming to a head it may track into the breast. It usually comes where staphylococcal infection is already present in the family. It does not cause a rise in temperature and although it can sometimes be aborted by early antibiotics it usually has to discharge before it is cured. It contains pus as soon as it has any body. For prevention a germicidal soap should be used for the washing of the trunk when either the baby or the mother has a staphylococcal lesion. Treatment consists of incision as soon as possible. The course of lactation is only altered by it if the lesion is too close to the nipple or the abscess is allowed to penetrate into the breast.

Intra-mammary mastitis is quite a different disease. It can be characterized by pain, tenderness, a flushed area, a febrile response, a decrease in secretion and there is always a lump. The curious thing about it is that in the early stages if the lump is emptied the condition is usually cured. While the lump is there the patient is liable to have rises of temperature of moderate or considerable severity; rigors are common. The assumption has so often been made that the fever must have a bacterial origin, but this is hard to accept for if the lump is emptied only milk is obtained and emptying brings cure. A careful hunt for organisms by blood culture has failed to find any but if infection comes, the infecting organism is always the staphylococcus. In many years of watching I have never seen a pyæmic abscess result and it seems hard to postulate two organisms, one making the initial febrile stage, the other being a staphylococcus which leaves no trace of the first, or, alternatively, that staphylococci can cause rigors commonly and not cause pyæmia.

A more reasonable explanation of the temperature rise is either that absorption of pyrogenic substances from the pent-up milk can occur—and there are constituents which can reasonably be suspected—or else the distension of the mammary gland causes a neurogenic pyrexia. The patient gives the appearance, as the temperature goes up, of having had an incompatible transfusion. When one remembers the hunt for germs which used to go on when a patient's temperature rose during transfusion before pyrogens or rhesus incompatibility were recognized, legitimate doubts are raised about infection as the immediate diagnosis in the early pyrexia. The raised temperature of early engorgement and of primary acute intra-mammary mastitis are thought to be of a kind.

The clinical finding that if the lump is emptied out immediately resolution is complete but if it is left unemptied for two days it becomes unemptiable now has some experimental backing. Silver has found that in mice if a mammary duct is ligated the capillaries of the blocked alveoli seal off and necrosis sets in. Emptying would then be impossible as the normal process involving blood-borne pitocin could not act.

Intra-mammary mastitis then is pictured as an unemptied part of the gland, increas[illegible]

tension within causing local signs and, by absorption or distension, a febrile response. After two days the chances of cure by emptying become small and staphylococcal infection almost inevitable. Because of the time limit on emptying, treatment is urgent. It consists of an antibiotic cover for, if infection comes, it will be with staphylococci. Emptying of the breasts should be undertaken by putting the baby to the breast, by hands or, most easily, by the Humalactor. Feeding from the breast should usually be continued for two days and then if the condition is not improving lactation must be suppressed. If infection comes lactation should be suppressed as far as possible before incision as otherwise fresh areas of unemptied breast tissue extend the area of mastitis and in turn await infection.

Preventive measures consist of those which ultimately keep the breasts empty. They start with the antenatal preparation, with shields if necessary since they help a baby to feed vigorously. Routine doses of stilbœstrol immediately after delivery help to avoid engorgement. During lactation lumps in the breast should be emptied and mothers should be taught to watch for them. Extra care is needed whenever the secretion is liable to be greater than the baby's demands, where secretion is excessive, the baby indisposed or where supplementary feeds are being given. Above all, breasts must be kept empty while lactation is being suppressed.

**Dr. David Morris:**

The preparatory techniques for breast feeding introduced by Dr. H. Waller at The British Hospital for Mothers and Babies at Woolwich, have made us familiar with some of the factors which impede or aid successful lactation.

Routine ante-natal examination of the breasts ensures the early diagnosis of such anatomical abnormalities as retracted nipples and their treatment with glass or plastic shells. Likewise the detection of inelasticity of the skin forewarns of the possibility of engorgement and its prevention by the early use of stilbœstrol. Manual expression taught ante-natally and practised during the last four to six weeks of pregnancy enables mothers to express without difficulty surplus milk after the baby has fed and thereby avoids rising tension and inhibition of further milk flow. In such conditions as prematurity or birth injury lactation can be established and maintained in spite of the baby's condition.

Breast feeding in present-day society appears to be a task of some difficulty requiring help, guidance and encouraging support in the lying-in period. Many of the failures of breast feeding are due to a lack of adequate supervision and preparatory training. The cracked nipple detected before skin erosion occurs is a common example of an avoidable cause of failure of breast feeding.

The recent survey carried out at Woolwich in conjunction with the sociology department of Bedford College illustrates what can be achieved. In contrast to the national trend of 41% of women fully breast feeding at 8 weeks, 69% of women discharged from hospital fully breast feeding were still doing so at 3 months, and 46% at 6 months.

Little is still known of the cause of failure of lactation in those apparently successfully breast feeding but it may well be that social trends and the ready recourse to bottle feeding is largely responsible. The increasing tendency to introduce early mixed feeding may also be an important factor.

Dr. H. F. Welbourne's study "Bottle Feeding: A Problem of Modern Civilization" amongst the Baganda tribe in Kampala, Uganda, illustrates the influence of the availability of bottles and dried milk. She found an increase from 14% to 30% in five years of supplementary bottle feeds before 6 months with a significant higher incidence of respiratory and bowel disturbances in those bottle fed. The weight gains were 1–2 lb. higher in those fully breast fed.

It is too quickly assumed that women do not wish to breast feed and unless pregnant

mothers are helped ante-natally, and during the lying-in period they may well abandon breast feeding without giving themselves a fair trial. The old reasons for advocating breast feeding, namely the avoidance of respiratory and bowel infections are no longer tenable. But recent work (Sinclair, 1957), and the increasing knowledge of the psychological importance to both mother and child necessitate a closer critical view than is at present held.

**Dr. Joan Ferreira:**

My point of view has developed while working in maternal and child welfare clinics. For fifty years these clinics have been trying to promote breast feeding, and it is disconcerting to find it steadily declining.

Ross and Herdon (1951) at Bristol found that the incidence of babies breast fed at three months fell from 77% to 36% between 1929 and 1949. During this period the proportion of babies attending welfare centres rose from 27% to 83%.

In recent years attendances at welfare centres over the country as a whole have dropped very slightly, but a large majority of babies do attend. In spite of this it is estimated that less than half, perhaps only a third of babies are breast fed at three months. Reports of various surveys show regional differences and also much greater success in groups having special help, e.g. at Woolwich, and Naish (1949) in her own practice.

The number of babies leaving hospital fully breast fed has also dropped, falling from 86% in 1950 to 76% in 1955. It is interesting to note that only 66% leaving the London undergraduate teaching hospitals were fully breast fed in 1955. I wonder whether this indicates increased readiness to allow mothers to make a choice about the method of feeding, and if so whether more are deciding not to breast feed. The drop may be accounted for partly by a greater tendency to send slightly doubtful cases out on complementary feeds. If so, it is a good sign, as distress in the first week after discharge will be avoided and lactation encouraged.

In all the surveys on lactation at least one-third of mothers were breast feeding; with special help, two-thirds or more were doing so. Nearly one-third are discharged from hospital having failed to breast feed adequately. It looks as though there is a middle third which can be influenced either way by the quality of the preparation and care given.

How might the welfare clinics have done better? I think the teaching given to mothers could have been more effectively and imaginatively done and more widely disseminated. Perhaps the advice given and methods used have at times been at fault. Wickes (1952) criticized these when he pointed out that welfare clinics frequently failed to recognize underfeeding, and in fact tended to induce it by their fear of overfeeding. New ideas are not always acceptable, and it took time for rigid feeding methods to be relaxed. There may have been pressure to continue unsatisfactory breast feeding where efforts to improve the situation had not succeeded. An anxious mother and frustrated baby will harm the attitude of other people towards lactation. Lastly there has been dissipation of effort where the work of the clinic staff has been unrelated to the family doctor.

A woman's emotions are often unstable during the first month after childbirth. She is readily given to tears, feels acutely moved by anything bearing on the baby, is indecisive and finds difficulty in taking responsibility and organizing her household. In order to mother her baby successfully she needs mothering herself. It is important that health visitors and midwives appreciate the kind of care that is needed, particularly in the case of first babies, when the pattern is being set for the rest of the family. Many babies seem to be taken off the breast unnecessarily during this period because of undue anxiety about their progress, misplaced fears about the condition of the mother and want of a little encouragement to persevere. Midwives and health visitors could do much to prevent this.

There should be no break in the care of hospital-confined mothers after they get home and the health visitor should make herself readily available. If possible she should be known to the mother previously, and some hospitals (with the permission of the mother) send information of bookings so that mother and health visitor can get to know each other in good time. Visits should be made at times when they can be most effective and the whole

family should be taken into account, for they are all influencing the outcome of lactation. Midwives and health visitors seem to deal with lactation largely on their own, and I think this may be partly the fault of the medical profession. More interest from the doctor might help to establish more successful nursing couples.

The numbers attending local authority ante-natal clinics have dropped sharply since the National Health Service began, so that clinical care of the breast in pregnancy is a responsibility which is passing elsewhere. If arrangements are reorganized in the future and lead to more continuity of care, this should favour the promotion of lactation.

It has been suggested that the time is coming when patients will cease to attend for clinical examination, and that the clinics will become centres where expectant mothers can learn about the confinement and care of the baby. There is a special need for mothercraft teaching to-day because with smaller families and women working outside the home, girls grow up having little idea of what will be required of them. At present mothercraft classes are held in many clinics by midwives and health visitors but on the whole only a few interested women attend. If all doctors and hospitals caring for primigravidæ appreciated the need for preparation for motherhood, and were satisfied about the quality of the teaching and supervision given, most women would be encouraged to attend.

The planning of the teaching should be personal and understanding. Common difficulties and early discomforts in breast feeding should be discussed and attitudes towards it ventilated. Tact and subtlety have to be used, as it must be recognized that some women will not succeed in lactating. The pleasure and not the duty of suckling ought to be stressed. Although the midwife and health visitor should be the key workers, they should have the support of those members of the medical profession best able to help. There is more to be known about the factors which influence lactation, and mothercraft classes offer a good medium for investigating some of these.

Many factors will have influenced the performance of the breast in lactation before pregnancy starts. As Wickes and Curwen (1957) have shown in comparing breast feeding performance of mothers and daughters, there may be a hereditary factor in ability to lactate. Since bottle feeding has become safer babies of poor lactaters are more likely to survive and pass on this characteristic. The mother's feeding experience in infancy, her growth, nutrition and education and the example of her own mother, will have influenced her abilities and outlook.

Several workers have shown a social class difference in breast-feeding performance, women in the higher classes being more successful. Westropp (1953) felt this emphasizes the need for freedom from domestic worries in the early days of lactation. Hytten and Thomson (1955) suggest that good diet, ability to cope and the belief that breast feeding is best are factors. I have met with an attitude, occurring more commonly in women of Social Classes IV and V, that breast feeding is "not quite nice". Perhaps this is a lingering of the Victorian ideal of refined womanhood which has seeped slowly through society, or possibly it is an awareness of the sensual implications of breast feeding with an unwillingness to admit them. It may be just an acceptable way of expressing failure to breast feed. Many of the women would appear to be complacent about not fulfilling their feminine functions and give up suckling without regret. Some of them believe bottle feeding to be less trouble as the bottle can be propped in the pram. Others do not want to feel "tied" to the baby. Are these attitudes becoming more common and are they being fostered by our present-day society? There is incomplete understanding of women's sexual emotions. Newton (1955) has pointed out the relationship between a woman's attitude to menstruation, sexual intercourse, breast feeding and infant care. Some women feel that suckling their babies is one of the things they expect from life. Mothers who have fed their babies successfully always want to do it again. I am sure that helping a woman to nurse her baby is important to the well-being of both.

There are many ways in which more could be done to encourage lactation. I have only touched on some of those which come within the orbit of the local health services.

## DISCUSSION ON THE COMPLICATIONS OF STEROID THERAPY

**Dr. J. P. Currie** (Glasgow):

The conditions modifying the action of drugs may be summarized thus:

(1) Form, purity and solubility of drug.
(2) Time of administration.
(3) Dose.
(4) Mode of administration.
(5) Rate of uptake.
(6) Efficiency of distribution.
(7) Rate of degradation or inactivation.
(8) Rate of excretion.
(9) Species peculiarities.
(10) Idiosyncrasy.
(11) Cumulation.
(12) Tolerance.
(13) Habituation.

Since these are the factors which may influence the therapeutic efficiency of a drug it follows that they are also the factors concerned in the appearance of the so-called toxic effects.

The matter is, however, more complex than this. It has been demonstrated that substances accepted as being pharmacologically inert are capable of producing "toxic" reactions.

For the purposes of the following examples, "toxic reaction" may be defined as an abnormal subjective or objective phenomenon appearing during the administration of a drug, disappearing promptly on discontinuing the drug and reappearing on subsequent administration.

| No. of patients | Drug | Reaction | |
|---|---|---|---|
| | | Subjective | Objective |
| 100 | Lactose 5 grams | 19 | 4 |

| Nature of reaction | No. of patients |
|---|---|
| Headache | 12 |
| Insomnia | 4 |
| Drowsiness | 2 |
| Itch | 1 |
| Blurred vision | 1 |
| Nausea | 8 |
| Vomiting | 2 |
| Proteinuria | 2 |
| Skin erythema | 2 |

If the medication is administered by injection, however, the incidents of "toxic" reactions increase thus:

| No. of patients | Drug | Reaction | |
|---|---|---|---|
| | | Subjective | Objective |
| 100 | 2 ml. sterile saline I.M. weekly | 34 | 9 |

| Nature of reaction | No. of patients |
|---|---|
| Headache | 16 |
| Insomnia | 6 |
| Drowsiness | 11 |
| Dysuria | 3 |
| Vomiting | 5 |
| Diarrhœa | 1 |
| Proteinuria | 3 |
| Erythema and urticaria | 3 |

Quite obviously, if results of this kind are obtained when using an inert "control" substance, the toxic effects of a known or experimental drug must be measured against such a background and not against an ideal of complete freedom from toxicity.

The appraisal of new drugs is rightly in the hands of practising clinicians, but it is regrettable that so often they appear to lack an adequate knowledge of pharmacodynamics. The modern pattern of our profession's reactions to a new therapeutic substance seems to follow a well-worn path, thus:

(1) Introduction with cautious claims of therapeutic advantage.
(2) Enthusiastic and laudatory papers confirming original claims.
(3) Toxicity reports—ranging from insomnia to sudden death, especially,
  (*a*) blood dyscrasias with special reference to agranulocytosis and aplastic anæmia.
  (*b*) liver dysfunction and jaundice.
(4) Gradual acceptance or abandonment of the drug.

In recent years one has seen this pattern followed with many drugs, among them sulphonamides, thiouracil, chloramphenicol, phenylbutazone, chlorpromazine, and Dichlorophen.

Few drugs produce a specific desirable effect free from side-reactions at any dose level – an example is vitamin C. Fortunately, most have a wide latitude of therapeutic action. That is to say, the effective therapeutic dose is very much lower than the toxic dose for the same drug.

It should be appreciated that toxic reactions recurring during drug therapy may occur in two ways:

(1) As an inherent property of the drug.
(2) As a peculiarity in response by the patient.

The "steroids" used in the treatment of the rheumatic diseases, usually designated the adrenocortical steroids, belong to the group of "$C_{21}$-steroids". They are thus closely related to the other steroid hormones chemically—and this is reflected in their biological relationships also. Thus in adrenalectomized animals the sex hormones have a distinct life-prolonging effect.

It is important to remember that most of the known adrenocortical steroids have the same qualitative effects and differ from one another only quantitatively. The distinction drawn between "mineralo-" and "gluco-" corticoids could only be appropriate when comparing the two extremes of Cortexone and cortisone. The effects of the adrenal steroids may be summarized thus:

(1) Lymphatic involution.
(2) Inhibition of connective tissue proliferation.
(3) Gastro-intestinal effects.
(4) Inhibition of inflammatory, allergic and reactive processes.
(5) Influence on carbohydrate metabolism.
(6) Influence on water and electrolyte metabolism.

Obviously for therapy in the rheumatic diseases we wish to make use of 4 and to a less extent of 1 and 2 above. We particularly wish to avoid effects 5 and 6.

With these requirements in mind two recently introduced synthetic steroids appear most nearly ideal, i.e. prednisone and prednisolone both of which have marked antiphlogistic properties with only minor electrolyte activity.

Unfortunately, some of the most undesirable steroid effects appear to be related to the gluco-corticoid and not the mineralo-corticoid effect, so that the potential of these drugs for producing gastro-intestinal ulceration, delay in wound healing and masking of serious infection remains. Even psychosis, which was at one time thought to be related to interference with potassium distribution appears to be a gluco-corticoid effect.

It has to be remembered that when undesired toxic effects result from the use of a drug the physician and not the drug is most frequently to blame for he should have been aware of the hazards from a knowledge of the pharmacodynamics of the therapeutic weapon he employs.

**Dr. John H. Glyn** (London):

*Incidence—Case Selection—Contra-indications*

A review of the world literature on this subject reveals startling discrepancies in the reported incidence of side-effects occurring during maintenance steroid therapy. Figures ranging from 0–86% have been quoted for *major* side-effects and 33–100% for *all* side effects. These discrepancies have been tabulated and some of the reasons for them discussed

elsewhere (Glyn, 1957). To some extent they can be explained on a purely semantic basis since a side-effect which some would describe as "toxic" would be accepted by others as an *essential—if unwanted—physiological* response to any "glucocorticoid".

Successful maintenance therapy ultimately depends on the balance between the susceptibility of the pathological and non-pathological tissues to the hormones. This balance is *quite impossible to predict in individual* patients but as between different *groups* it is possible with some confidence to anticipate which will incur most problems. Case selection should be based not only on these considerations but also on the prognosis if steroid therapy is not given; hence the importance of recent studies by Duthie *et al.* (1957) on prognostic factors in untreated rheumatoid disease.

Another well-recognized and perplexing fact is that an individual does not necessarily develop the same complication on two successive and apparently identical courses of steroid therapy. Similarly it is not safe to predict the type of complication he will get on the basis of his previous susceptibilities. These points were well made by Lewis and Fleminger (1954) in the psychiatric field but they are equally true in other fields. A possible explanation of these clinical inconsistencies was given by Browne in 1951 when he illustrated that tissue responses to these drugs vary considerably according to the prevailing "milieu interne" of the cells of those tissues.

Now that tuberculosis can be well controlled by appropriate drugs given in association with steroids, there would seem to be no longer any *total contra-indications* to steroid therapy and each case must therefore be assessed according to its *relative* indications and according to the limits of our fallible experience in predicting the expected benefits.

### *Dosage*

Since the incidence and seriousness of side-effects is intimately related to the maximum maintenance dose which is permitted it is important to note that policies on this point vary greatly. Most European centres (e.g. Copeman *et al.*, 1954) state that the incidence of serious complications rises very steeply above a dosage of 75 mg. cortisone/day (or its equivalent of the delta derivatives). Accordingly, they recommend that this should be the maximum permitted dosage. Several centres, working independently of each other, found that the *average* dose in their long-term series worked out at 69·5 mg. cortisone/day. In striking contrast to this, the Mayo Clinic physicians (Polley, 1956) recommend a daily maximum of 30 mg. cortisone for post-menopausal females, 37·5 mg. for younger women and 50 mg. for men. On this regime they claim virtually to have eliminated serious complications but it would seem to some that in many severe cases this can only be achieved at the expense of effective suppression of signs and symptoms.

### *Preparations for Steroid Therapy*

Unless a short course of treatment for a specific purpose is planned, the decision to start a patient on steroids is a major one and should never be taken without full consideration of the implications of long-term and possibly permanent suprarenal suppression. Many clinical, sociological and even economic factors must be evaluated in advance if disappointment and potentially difficult weaning processes are to be avoided. The intelligent co-operation of the patient should be sought and he should have some of the pros and cons explained to him. A careful baseline of objective measurements should be made before treatment commences so that the benefit to him can be accurately evaluated from time to time and the treatment terminated or modified as soon as it seems to be losing its good effect. Above all these drugs must never be used casually or merely as analgesics.

### *Some Specific Complications*

(i) *Steroid "tolerance".*—The concept of the development of tolerance to these drugs is admittedly a controversial one with which to head a list of specific complications. Many would deny that such a condition exists and would argue with conviction that there are many alternative and more satisfactory explanations of the clinical relapses which many patients gradually suffer—despite constant dosage—after the first few months of administration. Hench and Ward (1954) discuss some of these possible mechanisms and Slocumb's (1952) conception of "hypercortisonism" may explain other apparent relapses. Whilst agreeing that there are several possible mechanisms to explain this phenomenon, personal experience suggests strongly that simple drug tolerance can and does frequently develop and indeed that it is probably the most important single cause of the disappointing results of the Empire Rheumatism Council (1955) and Medical Research Council (1957) controlled trials in which cortisone was evaluated against aspirin.

It has been suggested by West (1957) that the relatively better results in the more recent trial in which prednisone was compared to aspirin were due to the greater difficulty experi-

enced by the tissues in adapting themselves to this more "unnatural" steroid. Certainly it is common experience that a patient who has become apparently refractory to cortisone may respond gratifyingly if he is switched to the delta derivatives in corresponding dosage.

In contrast to this, the development of a true resistance to corticotrophin with measurable circulating antibodies is a well-recognized phenomenon. Again the problem may sometimes be overcome by switching to corticotrophin derived from another animal species.

(ii) *Polyarteritis.*—It is now realized that a polyarteritic reaction may be found in biopsy material in about 30% of rheumatoid arthritics irrespective of the treatment they receive. This reaction appears to occur more frequently, in a more necrotizing form, and to be far more widespread in certain patients treated with steroids, especially in those in whom the dosage has been varied too rapidly. Allied to this and of doubtful significance is the acknowledged increase in the proportion of rheumatoid arthritics who show a positive L.E. cell phenomenon when their blood is tested. It is too early yet to be sure of the ultimate fate of these patients, and perhaps one should regard it as an "interesting observation" rather than as a "complication" until this point is settled.

(iii) *Obesity.*—All of the steroid drugs which are used in the treatment of the rheumatic disorders tend to produce abnormal deposits of fat and generalized obesity. Many metabolic factors are concerned in this process. There is also frequently a marked increase in appetite. Since it is so much easier to avoid a patient becoming overweight than to reverse this once it has occurred, it is a wise plan to warn patients of the possibility and to be very strict with them on their initial visits. The problem is slightly less difficult now that the delta derivatives have virtually eliminated sodium retention as a contributory factor.

(iv) *Diabetes* is a relatively infrequent complication (Bishop and Glyn, 1952). There is now universal agreement that it demands a reappraisal rather than the abandonment of steroid therapy in most cases but that every effort should be made to keep the blood sugar under control despite the usual absence of ketosis in this condition.

(v) *Physiological* suprarenal atrophy both during, and for several months after, prolonged steroid therapy is now a well-recognized potential complication unless the appropriate prophylactic measures are taken if the patient meets with any unaccustomed stress. It is strongly recommended that patients carry a card warning any physician or surgeon, who may attend to them casually, that they are receiving these hormones and referring them to an appropriate source of information should they not be aware of these measures.

(vi) *Pregnancy.*—In the dosages now being used, the dangers of producing a malformed fœtus by administering steroids throughout pregnancy if necessary seem to be hypothetical rather than real. Certainly high dosages should not be given except as a life-saving measure. It is interesting in view of the controversy which surrounded this subject in the early days to learn that cortisone has many protagonists as the treatment of choice in cases of toxæmia of pregnancy and it has even been recommended as an aid to conception in cases of relative infertility!

## *Conclusion*

The complications of steroid therapy should be, as Hench once said, "respected rather than feared". As they become recognized and understood, adequate prophylactic measures tend to become available. The secret, as with all complex forms of treatment, is adequate and frequent supervision so that all the side-effects may be tackled in their early stages. This is naturally of particular importance while the patient is being initially stabilized, but throughout the whole of his treatment it is my opinion that no patient should be seen less frequently than once every six weeks, and at each visit he should be routinely and comprehensively surveyed for possible early complications.

**Dr. F. V. B. Morton** (Nottingham):

With the co-operation of clinicians in various hospitals we have undertaken limited studies on the incidence of and the reasons for peptic ulceration during steroid therapy, in an endeavour to suggest preventive action.

One must, firstly, differentiate between proven peptic ulceration and "dyspepsia" where the presence of actual ulceration has not been shown. This dyspepsia is common during steroid therapy.

Table I gives a rough idea of the figures for the incidence of ulcer in the normal populations of different groups of countries. From Table II it would appear that a slightly higher incidence of peptic ulcer is found in patients suffering from rheumatoid arthritis. This could presumably be due either to aspirin or phenylbutazone therapy or to an inherent tendency for rheumatoid patients to develop ulcer.

TABLE I.—INCIDENCE OF PEPTIC ULCER IN GENERAL POPULATION

TABLE IV.—INCIDENCE OF PEPTIC ULCERS (INCLUDING HÆMORRHAGE FROM UNKNOWN SOURCE) FOLLOWING TREATMENT WITH CORTICOTROPHIN AND ADRENOCORTICAL HORMONES

| | | | |
|---|---|---|---|
| Corticotrophin | 4 incidents in 299 patients | = 1·3% |
| Cortisone | 22 incidents in 404 patients | = 5·5% |
| Hydrocortisone | 1 incident in 65 patients | = 1·5% |
| Prednisone | 6 incidents in 94 patients | = 6·4% |
| Prednisolone | 8 incidents in 161 patients | = 4·9% |
| Prednisone or prednisolone | 0 incidents in 11 patients | = 0 |

incidence of peptic ulcer in patients receiving different types of steroid therapy. Comparison is difficult because the type and duration of therapy varies, and in the later British series smaller doses and more cautious therapeutic regimes were employed. Bunim's 4 patients who developed ulcer while on delta compounds all received more than 20 mg. daily, as did Kern's 3 patients. None of Kern's 54 patients receiving less than 20 mg. daily developed ulcer. Table III also shows that there is a considerable variation in the ulcer incidence reported by various workers. In one British unit where large doses of prednisolone and cortisone were given to children the incidence of ulcer was 10%. Hydrocortisone appears to give a lower incidence. The impression that corticotrophin results in a lower incidence of ulcer is confirmed by a perusal of the published reports (Savage *et al.*, 1957; West, 1957). The difference between cortisone and prednisolone and prednisone is probably not significant, provided that the difference in potency is remembered. From a study of Table V

TABLE V.—SITE OF ULCERATION

| Treatment | Gastric ulcer | Duodenal ulcer | Both gastric and duodenal ulcers | Gastro-duodenal hæmorrhage | Unknown |
|---|---|---|---|---|---|
| Corticotrophin | 2 | 1 | | 1 | |
| Cortisone | 5 | 9 | | 7 | 1 |
| Hydrocortisone | 1 | | | | |
| Prednisone | 2 | 3 | | 1 | |
| Prednisolone | 4 | 2 | 2 | | |
| Totals | 14 | 15 | 2 | 9 | 1 |

which shows the site of ulceration in relation to the type of steroid used, it is seen that the total incidence of gastric ulcer seems to be approximately the same as duodenal ulcer. As duodenal ulcer is generally more common than gastric it is suggested that the absolute incidence of gastric ulcer is increased. Severe gastric hæmorrhage has been reported in the absence of any detectable localized ulcer, but so also has a type of gastric ulcer which appears to be confined to patients being treated with steroids. These ulcers are of a very acute type, serpiginous and often shallow, with minimal reaction in the surrounding tissues, and often perforate or bleed.

It seems that there may be two types of peptic ulcer which arise as a result of oral steroid therapy: (*a*) The "conventional" duodenal ulcer arising during long-term therapy and possibly associated with alteration in the gastric secretion. Sudden perforation or hæmorrhage may occur as a result of steroid therapy. (*b*) Acute "steroid-induced" gastric ulcers resulting directly from the local action of high concentration of steroid on the gastric mucosa as well as from the systemic action of absorbed drug.

Many conflicting statements have been made with regard to the effect of steroids and adrenal stimulation on the gastric secretion of acid, pepsin and mucin. The evidence available suggests that the increased secretion of acid and pepsin is not necessarily related to the production of ulceration. The decrease in the viscosity of the secretion, reported by some workers, is interesting in view of the suggestion that gastric mucin has a protective action on the mucosa. Such an effect of steroids might be connected with their action on the mucopolysaccharides of synovial joint fluid. It seems more reasonable to suppose that the fundamental alteration in the cell reaction is responsible for the development of peptic ulcer; in other words, that the ulcerogenic tendency of a steroid may be in fact inherent in the therapeutic properties of the drug.

All these factors may be important in the ætiology of steroid-induced ulcers, but it does seem that the reaction of gastric mucosa to high local drug concentrations achieved during oral

therapy may be of the greatest significance. It was thought that enteric-coated tablets or capsules might be a means of avoiding this local factor as the gastric mucosa might be protected in this way from high concentrations of steroid, and it is known that the small intestine is relatively immune to ulceration.

It was necessary in the first place to find out whether satisfactory absorption was obtainable, and in conjunction with Dr. West of Sheffield studies were carried out with two preparations —shellac-coated tablets, and capsules made of formalin-treated gelatin. Figs. 1, 2 and 3

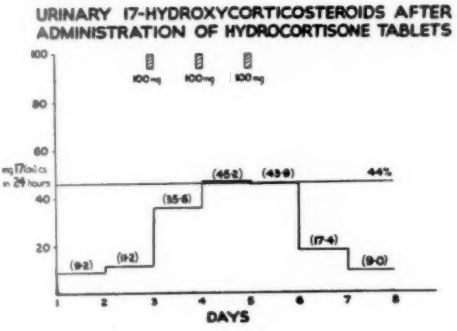

FIG. 1.

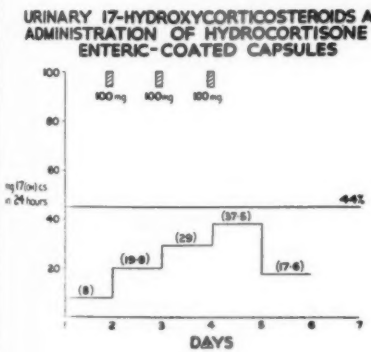

FIG. 2.

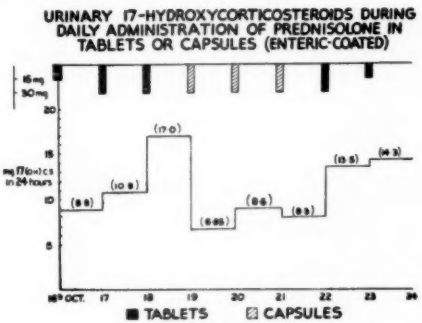

FIG. 3.

show the results obtained by measuring the urinary 17-hydroxycorticosteroid excretion after administration of corticosteroids by mouth. In this laboratory an average recovery of about 44% is expected in a normal individual, and a recovery of less than 44% is considered unsatisfactory. Absorption was found to be variable, but defective in a number of subjects, and patients previously controlled with orthodox prednisolone tablets also had a recurrence of acute joint symptoms when the enteric-coated tablets were administered. These results were disappointing, and it was concluded that absorption of both hydrocortisone and prednisolone from the enteric-coated capsules and tablets used in these experiments was unreliable.

*Summary*

(1) Peptic ulcer with symptoms occurs in a greater number of patients receiving steroid therapy than in a control group. Perforation and hæmorrhage are frequent and severe complications. If proper allowance is made for differing potency, the delta analogues probably give rise to the same number of ulcers as cortisone.

(2) It is suggested the ulcerogenic action of these steroids when given orally is due at least in part to a more powerful local action on the gastric mucosa as well as to the systemic action on cellular function. It is possibly for this reason that injected corticotrophin is less likely to give rise to gastric ulcer than oral steroid administration.

(3) Attempts at modifying the formulation of hydrocortisone and delta-hydrocortisone by means of enteric-coating, in the hopes of ensuring adequate absorption but mitigating the ulcerogenic effect have been unsuccessful.

*Acknowledgment*

I would like to acknowledge with grateful thanks the invaluable assistance given to me by Mr. Raymond Cobb, B.Sc., in the preparation of this paper. I would also like to thank Dr. W. I. Card for his help and for kindly providing material for slides; and Dr. Harry West for allowing me to present results that were obtained in his Unit; and the following for providing data for the analysis of incidence of peptic ulcer during steroid therapy: Drs. Logie Bain, Stuart Barber, Bywaters, Duthie, Dudley Hart, Fletcher, Kellgren, Kersley, Savage and West.

The enteric-coated capsules and tablets used in the studies referred to were provided through the courtesy of Boots Pure Drug Company.

# Section of Dermatology

President—JOHN T. INGRAM, M.D., F.R.C.P.

[*October* 17, 1957, continued from March *Proceedings*, p. 175]

Dr. J. T. INGRAM delivered a Presidential Address on **Famous Dermatologists of the Past.**

[*November* 21, 1957, continued from March *Proceedings*, p. 176]

**Scleredema [Buschke].**—C. M. VESEY, M.R.C.S., L.R.C.P. (for C. D. CALNAN, M.R.C.P.).

V. A., female, aged 29.

*History.*—July 1957: Sudden onset of stiffness of the neck. The stiffness and hardening of the skin spread rapidly over the front of the chest and down to the scapulæ.

She had a mild sore throat about a week previously.

*On examination.*—There is a hardness and swelling of the skin over the neck and front of the chest from the jaw-line down to the 3rd rib, and to a similar level at the back. There is little visible change except for a shiny appearance, and pitting œdema is absent.

No abnormality was found on general examination.

*Investigations.*—X-rays of chest and cervical spine, blood count, and sedimentation rate are normal. Creatine excretion is not increased. Anti-streptolysin titre 120 units/c.c. W.R. and Kahn negative. Rose's euglobulin test negative. Serum proteins normal except for slight increase in gamma globulin.

**Œdematous Scleroderma.**—C. D. CALNAN, M.R.C.P.

T. L., male, aged 52.

*History.*—Five months ago he began to complain of irritation and a rash on the front of his legs. He may have had hardening of the skin previously but the more recent blistering and œdema made him seek advice. About a month ago he had an attack of influenza and urticaria which has now subsided. He next developed a virus pneumonia. Since then his legs have become worse and he now complains of swelling and stiffness of his hands and stiffness of the upper arms and backs of the thighs.

*On examination.*—The lower legs are almost entirely covered by sclerodermatous skin, with pitting œdema and some hæmorrhagic bullæ. The œdema is in many places very superficial, like that found in lichen sclerosus et atrophicus. There are patches of hard skin without epidermal change on the thighs and arms and wrists. Œdema is present over the dorsa of both hands and the clenching of his fists is limited.

*Comment.*—This case contrasts well with the previous one of scleredema (Buschke) because some authors described the latter condition as œdematous scleroderma. This present case has in fact very œdematous scleroderma with gross pitting, œdema, bullæ and hæmorrhages. It is similar to a patient that I showed with Dr. M. Feiwel a few years ago.

**Alopecia Mucinosa (Pinkus).**—I. MARTIN-SCOTT, M.D.

MRS. S. H., aged 35. Housewife.

*History.*—Early in March 1957 this woman developed two circinate scaly lesions on the nape of the neck which were slightly irritant. She lives on a farm. In August she noticed her eyebrows became slowly swollen, and about one month later the hairs were shed. Gradually this tissue swelling appeared on her cheeks and chin. Her general health throughout had been good.

*Past health.*—Uncomplicated chicken-pox, whooping-cough and measles in childhood. Two children aged 7½ and 1½ years.

*On examination* (2.9.57).—There were two circinate scaly patches in the nuchal area which resembled tinea circinata. There was no fluorescence under Wood's light, and examination of scrapings by Dr. Jacqueline Walker was negative for pathogenic fungi. These lesions were treated with Tineafax ointment and improved, but left in their wake a confluent area of keratosis pilaris devoid of hair. At this time she also had discrete symmetrical indurated swelling of the eyebrows and chin with hair loss, erythema and superficial fine scaling. The follicular ostia were patulous.

When seen on 1.10.57 these firm swollen areas had become more diffuse and extended down her cheeks to the sides of the neck; and by the end of the month, when the biopsy was done, symmetrical small infiltrations were present on both elbow folds. In December 1957 the skin infiltration became less prominent, but involved most of the facial skin excluding the eyelids and nose, but she had developed irritation of both arms, which was considered exogenous and quite unassociated with the main skin condition.

FIG. 1.—December 1957: This shows thickening and scaling of the skin. The eyebrows are lost, and the scalp hair is receding. The biopsy scar is seen on the left cheek.

*Investigations.*—Scrapings from the neck (2.9.57): No pathogenic fungi found. E.S.R. (4.9.57) 14 mm. in one hour (Wintrobe). Mantoux reaction 1/1,000 (4.9.57) negative. Tonsillar swab (4.9.57): *Streptococcus viridans* cultured. Blood count (4.9.57): No anaemia and normal white cell count. X-ray of chest (26.8.57): No abnormality detected. Biopsy from skin of cheek, 29.10.57 (Dr. Charles Pike, Watford): The essential process is a proliferation of the cells of the external root sheaths and sebaceous ducts. Between these cells are multifocal accumulations of a mucinous fluid, with formation of small cysts in places. This mucinous substance is metachromatic with thionine and stains with alcian green. It is, however, only weakly positive by PAS and muci-carmine staining. It gives therefore the reaction of a connective tissue mucin. In the corium around the affected hair follicles and blood vessels there is a light infiltration by lymphocytes with an occasional eosinophil and histiocyte. The epidermis shows a few foci of parakeratosis only.

*Treatment.*—During September 1957 she took 150 mg. chloroquine twice daily, and applied Tineafax ointment to the nuchal area. No treatment has been given since October 195

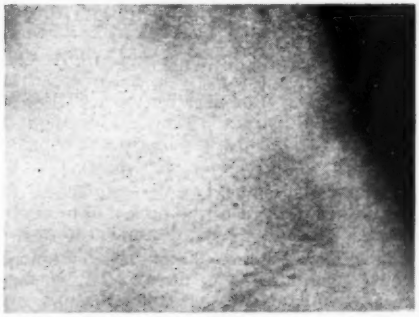

FIG. 2.—This shows the keratosis pilaris appearance in the nuchal area.

FIG. 3.—Low-power view (×15) showing follicular proliferation and loss of hair shafts. Cystic spaces are present in the pilo-sebaceous complex.

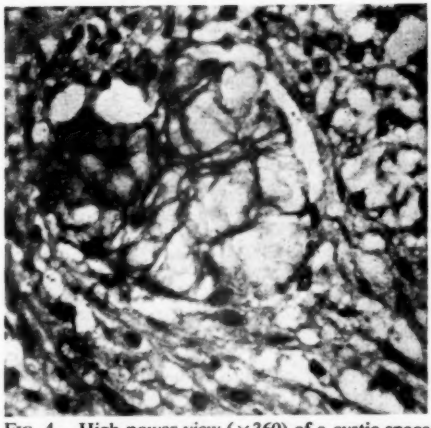

FIG. 4.—High-power view (×360) of a cystic space in the follicular sheath containing mucin.

Figs. 3 and 4 are stained with phloxine tartraxine and alcian green.

*Comment.*—This case is similar to six other cases recently published (Pinkus, 1957). Clinically at different stages of the disease process the features are surprisingly variable, and my case has presented the morphology of tinea circinata, keratosis pilaris, and in the early stages lupus erythematosus profundus with associated alopecia. Histologically the first stage appears to be a true cellular proliferation of some of the hair follicles associated with loss of hair. Next a mucin-containing fluid separates these cells and forms pools within the pilo-sebaceous apparatus, and the sebaceous glands disappear. The infiltration appears to be a reactive phenomenon, and in the cases reported varies from a few lymphocytes to a granuloma. The staining reactions of the mucin in this case are those of connective tissue mucin, which suggests a degenerative pathological process rather than an active metaplasia in which the epithelial cells actually secrete mucin.

POSTSCRIPT (February 1958).—The eczematous condition of the arms settled down in a week, and was probably due to a woollen cardigan. The skin of the face is now less thickened and more mobile, but there has been no regrowth of hair and the keratosis pilaris of the neck remains unchanged. There has been no extension of the disease for three months.

## REFERENCE

PINKUS, H. (1957) *Arch. Derm. Syph. Chicago*, **76**, 419.

**Dr. Brian Russell:** Dr. P. M. Deville recently asked me to see a patient with erythematous plaques on her cheeks. Biopsy showed the same mucinous degenerative changes in the sebaceous glands. I think a better term would be follicular mucinosis, because alopecia is not always seen.

**Normocholesterolæmic Xanthomatosis.**—P. F. BORRIE, M.D.

Miss M. M., aged 49. Stenographer.

*History.*—Two patches of yellow discoloration appeared at the corners of the eyes in 19[illegible]. Since then others have appeared on the face, scalp, neck and chest, some of which have slowly spread. The lesions have been stationary for the last three years. For the last four years she has been getting periods of pyrexia. They last for about five weeks at a time, are accompanied by little malaise, but the temperature may be as high as 101° F. at night.

*Past history and family history.*—Not relevant.

*On examination.*—There is a barely palpable, soft, well-defined yellow infiltration of the skin, confluent over the whole scalp, front of the neck and upper part of the centre of the chest, and patchy on the face. General physical examination showed no abnormality.

*Investigations.*—Serum cholesterol 250 mg./100 ml. Hæmoglobin 76%. R.B.C. 3,800,000. W.B.C. 4,000 (neutros. 49%, lymphos. 45%, monos. 5%, eosinos. 1%). E.S.R. varies between 40 and 70 mm. in the hour (Westergren). Plasma proteins (electrophoresis): Slight increase in gamma globulin.

Blood sugar (fasting): 122 mg./100 ml.

Liver function tests normal.

X-ray chest: Local bulge of ascending aorta, probably arteriosclerotic. Lungs, bones: Normal.

*Biopsy:* Xanthomatous deposit in the corium, most of the lipoid material being present in large foamy macrophages, amongst which there are numerous Touton giant-cells. Frozen section shows the sudanophil material to be doubly refractile: i.e. cholesterol.

*Comment.*—Cutaneous deposits of cholesterol associated with normal levels of cholesterol in the blood usually occur as small lesions on the eyelids (xanthelasma) or as xanthoma disseminata. In the latter form the nodules may be isolated, pedunculated or packed together. They occur mostly in the axillæ, antecubital fossæ or on the sides of the neck. Even where the individual lesions are packed so closely together as to appear confluent, stretching the skin always shows up the furrows between them. I have been able to find only two examples in the literature with a similar type of cutaneous lesion to the present case (Thannhauser, 1950). One was a man of 55 in whom the lesion covered nearly the whole body. He died two years later of multiple myeloma, but showed at post-mortem examination no other xanthomatous deposits. In the second case the xanthoma covered the whole of the scalp, but was associated with multiple petechiæ on the trunk and limbs, dural, cerebral and lymph-gland xanthomatosis and eosinophilic granulomata of bone. Although no evidence of other xanthomatous or granulomatous deposits has been found in the present case, the history of recurrent pyrexia and the consistently high E.S.R. suggest that these may, in fact, be present.

THANNHAUSER, S. J. (1950) Lipoidoses. 2nd edit. New York.

**Livido Reticularis.**—P. F. BORRIE, M.D.

Mrs. M. N., aged 37, housewife.

*History.*—1948 (one year after birth of last child): Red, tender, indurated nodules in right leg, diagnosed as phlebitis. 1951: Same condition in left leg. 1953: Development of livido reticularis, reaching its present extent in a year.

July 1955: Onset of ulceration while in Germany. Since then has had 3 further crops in Singapore in June, September and October 1956, and 2 in England in July and October 1957. The ulceration lasts one to two months. It begins with purpura and telangiectasis, proceeds to hæmorrhagic blister-formation and exquisitely painful superficial ulceration. The pain, which in the last attack needed heroin to control it, is worse with the leg up and with warmth.

*Past history and family history.*—Not relevant.

*Treatment.*—Vasodilators, lumbar sympathectomy, steroids, mepacrine with no effect. Two weeks ago fresh signs of impending ulceration occurred, which disappeared in a week with heparin 10,000 units six-hourly.

*Investigations.*—Full blood count, E.S.R., W.R., Kahn, plasma proteins, cryoglobulin and cold agglutinins, normal. L.E. cells—none. Muscle biopsy, and urinary 5-hydroxyindole and acetic acid: normal. Biopsy from base of ulcer: fairly marked obliterative endarteritis but this is compatible with changes secondary to the chronic ulceration.

*On examination.*—Livido reticularis from feet to waist and from hands to shoulders. Pigmented and depigmented, atrophic scars on feet and lower legs in sites of previous ulceration, some of the "atrophie blanche" type.

*Comment.*—This appears to be a good example of the primary vascular, as opposed to the symptomatic, variety of livido reticularis. A small proportion of these cases are worse in the summer and 12 almost identical cases were recently described by Feldaker *et al.* (1955). The treatment of choice was found to be bed rest, elastic bandages and hexamethonium. Sympathectomy was disappointing, but heparin was not tried.

REFERENCE

FELDAKER, M., HINES, E. A., and KIERLAND, R. R. (1955) *Arch Derm. Syph., Chicago*, **72**, 31.

**Gougerot's Maladie Trisymptomatique with Cryoglobulinæmia.**—D. C. G. BETT, M.R.C.P. (for STEPHEN GOLD, M.D.).

Miss P. C., aged 44.

*History.*—For three years she has had recurrent purpuric and urticarial-type lesions on her legs, accompanied by swelling of the ankles. In the last year a small ulcer developed on the lateral side of the right ankle, but this is now healing. Biopsy (October 1954) showed an acute arteriolitis compatible with maladie trisymptomatique (Dr. H. Haber).

*Previous history.*—In 1938 she had an infected parotid gland, and since then has had a dry mouth and also some dryness of the eyes, with occasional pain and swelling of the parotids. Since 1953 she has had attacks of stiffness, pain and swelling in the joints of her hands and in the knees and ankles, but this clears completely between attacks. She has been diagnosed as a case of Sjögren's syndrome. In 1953 she had sinusitis, but has had no recurrences. Since 1944 she has had carious teeth, but these were removed in 1955.

*On examination.*—No abnormality detected apart from the leg lesions.

*Investigations.*—Hæmoglobin 86%; W.B.C. 6,000, with normal differential count. Bleeding time: 2 minutes 30 seconds. Clotting time: 10 minutes 30 seconds. E.S.R. 32 mm. in the first hour (Westergren). No L.E. cells. Urine: No albumin, Bence-Jones proteose or sugar. Centrifuged deposit of epithelial cells and occasional polymorphs.

X-rays of chest normal. Bones and skull normal except for some general osteoporosis; no evidence of arthritis or myelomatosis.

Serum protein: Total 6·5; albumin 3·8, globulin 2·7, (alpha-one globulin 0·2, alpha-two globulin 0·5, beta globulin 0·6, gamma globulin 1·4) g./100 ml., cryoglobulins present.

*Comment.*—The cryoglobulin is present in very small amount, much less than occurs in multiple myelomatosis or essential cryoglobulinæmia. It precipitates fully after forty-eight hours at 4° C. and is thus unlikely to cause symptoms in cold weather. In this case the associated Sjögren's syndrome may be regarded as the cause of the cryoglobulinæmia, but another five cases of maladie trisymptomatique, seen at St. John's Hospital for Diseases of the Skin, have had serum proteins estimated and one of these also shows cryoglobulin. This latter case has been extensively investigated without finding any cause for the cryoglobulinæmia except the maladie trisymptomatique.

**Cryoglobulinæmia and Reticulosis.**—E. N. M. JOHNSTON, M.R.C.P., and H. J. WALLACE, M.D., F.R.C.P.

Mrs. M. S., aged 47.

*History.*—Since 1940 attacks of urticaria, described by the patient as itching hives, have recurred in cold weather. Since 1947 recurrent painful ulcers have been present on the legs. Painful discoloured patches appear and break down, leaving ulcers which are slow to heal. During the past six years Raynaud attacks precipitated by cold have affected the fingers. In 1951 bilateral lumbar sympathectomy was performed with apparently little influence on the occurrence of the leg ulceration. In 1952 left cervical sympathectomy produced only temporary relief of the Raynaud attacks. In 1953 an abnormal serum globulin was found but electrophoresis did not confirm the presence of cryoglobulin. Since 1954 courses of isoniazid and PAS have been given, a diagnosis of papulonecrotic tuberculide having been made. At times these drugs have appeared to accelerate healing. January 1957: X-ray of painful left foot showed arthritis of the subtaloid joint. A tuberculous aetiology was suggested. Subsequent X-rays have shown no abnormality. A course of streptomycin in August 1957 was followed by a toxic erythema and all antituberculous treatment was stopped and a course of deltacortisone was given. There have been no gastro-intestinal, cardiorespiratory, neurological or genito-urinary symptoms. There have been joint pains apart from pain in the left foot.

***Past history.***—1951: Pneumonia.

***Family history.***—The patient's three children and sister, all apparently normal, have been investigated for cryoglobulins. None was found.

***On examination.***—The lower legs showed healing ulcers, scarring, patchy discoloration, purpura and pigmentation. A moderate degree of cutis marmorata was present up the front of her legs. Peripheral pulses were present and there were no varicose veins. The hands showed sluggish circulation and shiny atrophic skin of the finger tips. The spleen was just palpable on inspiration. Small glands were present in the neck and axillæ. There were no other abnormal physical signs. The blood pressure was 105/65. No albuminuria or glycosuria was present.

*Investigations*

*Hæmatology.*—Hb 95%. W.B.C. 7,500, normal differential. E.S.R. 50 mm. in one hour (Westergren), 2 mm. in half hour, 22 mm. in one hour (Wintrobe); Platelets 170,000/c.mm. Osmotic fragility of red cells normal. Direct Race-Coombs test negative. No L.E. cells found on three occasions in peripheral blood. No cold agglutinins detected. Bone-marrow: "Marked increase in eosinophilic granulopoiesis but otherwise normal. No plasma cells seen. Very occasional intracytoplasmic deposits of blue homogeneous material are seen in the polymorphs and they may possibly represent deposits of phagocytosed cryoglobulin."

*Serology.*—W.R., P.P.R. negative.

*Biochemistry.*—Plasma proteins: Thymol turbidity 14 units, total protein 6·4, albumin 4·1, globulin 2·3 g./100 ml. Serum electrophoresis: low gamma with an increased alpha 1, beta, and intermediate band between beta and gamma globulins suggestive of the presence of cryoglobulin. This was confirmed by dissolving the cold precipitated protein and re-examining electrophoretically. Cryocrit estimation 14 units. Cryoglobulin estimated accurately (by micro Kjeldahl method) 0·5 gram%. Alkaline phosphatase 6·0 K.A. units, acid phosphatase 1·0 K.A. unit. No protein in urine.

*Radiology.*—Chest X-ray: no lung lesion. Left ankle: no definite bony abnormality. Barium swallow: no evidence to suggest scleroderma of œsophagus. Dilatation of the gullet just above the diaphragm thought to be a phrenic ampulla and no evidence of a hiatus hernia. No reflux could be elicited. Skull, spine, pelvis—no evidence of multiple myeloma deposits.

*Histology.*—An enlarged lymphatic gland was removed from the right axilla and was reported by Dr. I. W. Whimster as showing histological changes suggestive of a reticulum-cell sarcoma or typical Hodgkin's disease.

The following cases were also shown:

**Addison's Disease.**—Dr. R. M. B. MacKenna.

## Urinary Colloids [*Abstract*]

By N. F. MACLAGAN, M.D., D.Sc., F.R.C.P.

*Department of Chemical Pathology, Westminster Medical School, London*

THE colloidal properties of urine have attracted attention for many years and have formed the basis of two apparently contradictory theories of the pathogenesis of renal calculi. Thus Joly (1931, 1939) and Butt *et al.* (1952) consider that urinary colloids have a protective action by delaying the precipitation of insoluble substances. On the other hand Boyce *et al.* (1954) described in the urine of their calculous patients a gross excess of mucoprotein, which was assumed to act by forming an insoluble calcium complex.

Studies on urinary mucoprotein secretion previously reported from this department (Lockey *et al.*, 1956) indicated a slightly lowered excretion in certain cases of renal calculi and appeared to favour the first of these theories, but no general method for assessing the "protective colloid efficiency" (P.C.E.) of urine was available at that time. Such a method was accordingly devised in collaboration with Dr. A. J. Anderson and is published in detail elsewhere (Maclagan and Anderson, 1958*a*). In brief this method consists of adding solutions of calcium chloride and sodium phosphate to a buffered preparation of dialysed urine, followed by centrifugation under controlled conditions. The amount of phosphate remaining in the supernatant fluid is then estimated by a standard method and gives a measure of the protective colloid efficiency. Values for P.C.E., expressed as $\mu$g.P/100 ml. of dialysed urine, are normally from 0 to + 400 (240 $\pm$ 39) but may vary pathologically from — 200 to + 2,000.

In assessing the results it was found to be essential to separate cases with proteinuria from those without, as the presence of albumins and globulins was usually associated with abnormally high P.C.E. values. In 13 cases of renal calculi without proteinuria the results were slightly below normal (144 $\pm$ 46 $\mu$g.P/100 ml.) but the difference was not statistically significant, and only two of these cases gave results actually below normal limits. Most of the other pathological states studied gave a proportion of high values for P.C.E., a tendency which was particularly marked in rheumatism and cancer. A few abnormally low values were, however, also recorded, e.g. in peptic ulcer and in paraplegia. It was particularly noteworthy that no high values either for P.C.E. or for any of the colloidal constituents were recorded in cases of renal calculi without proteinuria.

Parallel with the P.C.E. tests, estimations of various colloidal constituents were made and the P.C.E. was found to be positively correlated with most of these such as nitrogen, reducing activity, sulphur, hexosamine, and sialic acid.

The results as a whole suggest that many different urinary colloids have some protective action in diminishing the precipitation of sparingly soluble substances, but no significant alteration in this property was demonstrated in cases of renal calculi. Equally, no increase of any colloidal substance seemed to be present, so that in this series at least there is nothing to support either of the two theories referred to above. It appears to be most important for any future studies of urinary colloids to take account of the dominating influence of clinical proteinuria, which, when present, is usually associated with an increased excretion of many proteins and mucopolysaccharides which must obscure the original picture.

A fuller account of these results will appear elsewhere (Maclagan and Anderson, 1958*b*). I am much indebted to the staff of the Westminster Hospital Group and also to Drs. A. R. Harrison and Barbara Billing for the collection of urine samples. The work was supported by generous grants from the British Empire Cancer Campaign and from the Endowment Funds of Westminster Hospital.

# Bilateral Orchidopexy and Fertility

By J. H. CARVER, T.D., F.R.C.S.

*London*

FEW papers have been published on the fertility of men who have had bilateral orchidopexy. This is not surprising as the operation even in children's hospitals is not a very common procedure and owing to the long interval between operation and the individual's marriage, contact between him and the surgeon is usually lost. The establishment of sterility clinics affords an opportunity to study the problem. At Hammersmith Hospital over 2,000 men have been seen at the Sterility Clinic between June 1946 and June 1957. 13 of these patients had bilateral orchidopexy. The operations were done at various hospitals in the United Kingdom and abroad (none was performed at Hammersmith) and details of the technique employed were unavailable in most cases. The position and size of the testes when seen at the Clinic and the results of semen analyses are shown in Table I. Of these patients only one operated on at 5 years of age at a Children's hospital was fertile. In this case the left testis was normal whereas the right was in the canal.

TABLE I.—SEMEN ANALYSES IN 13 ADULTS AFTER BILATERAL ORCHIDOPEXY

| Case No. | Age at operation | Gross appearance of testicles at fertility clinic | Semen analyses |
|---|---|---|---|
| I | 5 | Right in canal | 82 million per ml. |
| | | Left + | |
| II | 13 R | Right ¾ | 750,000 per ml. |
| | 14 L | Left ¾ | |
| III | 5 | Right + | Azoospermia |
| | | Left + | |
| IV | 10 | Right ¾ | ,, |
| | | Left ¾ | |
| V | 15 | Right ¾ | ,, |
| | | Left ½ | |
| VI | 12 R | Right + | ,, |
| | 15 L | Left ½ | |
| VII | 15 | Right ¾ | ,, |
| | | Left in canal | |
| VIII | 16 | Right ½ | ,, |
| | | Left ½ | |
| | | Both at external ring | |
| IX | 10 R | Right + | ,, |
| | 18 L | Left ¾ | |
| X | 12 | Right ¾ | ,, |
| | | Left ¾ | |
| XI | 15 | Right + | ,, |
| | | Left + | |
| XII | 17 | Right ¾ | ,, |
| | | Left ¾ | |
| XIII | 8 R | Right ¾ | ,, |
| | 13 L | Left ¾ | |

The second patient had severe oligospermia, 750,000 sperms per ml. He had a course of hormone treatment at the age of 6. Operation was performed on the right side at 13 and on the left at 14. Both testes were about three-quarters of the normal size.

Of the remaining 11 patients 1 was operated on at 5 and the others between 8 and 18. In Case VIII both testes were atrophied and were just at the external ring. In Case VII the right was in the scrotum and the other in the canal. The other 9 patients had satisfactory cosmetic results. All 11 patients were azoospermic. Biopsies were performed in Cases I, XI and XII.

Case II. In the left testis there was complete absence of spermatozoa and cell precursors. The Sertoli cells were prominent with hyaline thickening of the basement membrane of the tubules. On the right side the pattern was not so severe: there were some spermatids and spermatozoa with increased Sertoli cells.

In Case XI the right testicle showed complete atrophy of the spermatogonia with Sertoli cell replacement and on the left side only a quarter of the tubules examined had spermatogonia, the rest were lined by Sertoli cells. In Case XII the histological findings were failure of maturation on both sides.

Gross and Jewett (1956) reported 16 cases from the Boston Children's Hospital. Of these

12 who had the operation at 12 or under were fertile and 4 operated on between 10 and 12 were sterile. No mention is made in their paper of the size of the testes when adult life was reached. In their operation a wide retroperitoneal approach was used. The testes were gently restrained in the scrotum by a silk suture passed through the lower pole and connected to a rubber band secured to the thigh. All restraint was removed in six days. 15 other cases from the same hospital, operated on between 1900 and 1934, were collected by MacCollum (1935). In this group all the testes were in the canal or intra-abdominal and no scrotal fixation was employed. Of the 15, 11 were fertile, 2 of whom were operated on between 3 and 5, and the others between 7 and 11. Of the remaining 4 patients who were operated on at 11, 2 had azoospermia and 2 severe oligospermia. The combined figures from the Boston Children's Hospital show that 23/31 patients (77%) who had bilateral orchidopexy at 12 or earlier were fertile.

Sterility after bilateral orchidopexy can be due to:

(1) Intervention after irreversible changes have taken place.

(2) Faulty surgical technique producing injury to the blood vessels or the vas deferens.

(3) Constitutional defects in the testis.

There is much diversity of opinion as to the best time to operate. Romanis and Mitchiner (1952) do not advise operation before the 10th year and prefer to wait until the boy is 16. Handfield-Jones and Porritt (1957) see little reason for surgical treatment before puberty. Bishop (1949) holds that the testicle should be in the scrotum before the 12th birthday. In the United States the tendency is to operate much earlier and Campbell (1954) with a wide experience of pædiatric surgery prefers the age of 3. Those who prefer to operate at this time have been influenced by the work of Robinson and Engle (1954). They have shown that there is little histological difference between the undescended testis and the normally descended organ up to the age of 5 and then there is a definite slowing down of development. They believe that this retardation should be anticipated by operating before the age of 5 if no response is obtained to massive doses of gonadotrophin (4,000 units daily for three days).

In only 2 of the Hammersmith cases was operation performed at the 5th year. One patient was sterile and the other fertile. In the Boston series 2 were operated on between 3 and 5, and they were fertile, and the remainder were operated upon between the ages of 7 and 12. Presumably, therefore, the process of retardation is slow and may vary in degree and extent with each individual. This would explain the very satisfactory results in the cases operated on between 5 and 12. Another factor which cannot be ignored is that the surgeons at the Boston Children's Hospital were especially experienced in pædiatric surgery.

Apart from damage to the vas deferens and blood supply during the operation, thrombosis of the vessels can occur from forcible attempts to maintain the testis in the scrotum. No restraint was employed in the MacCollum series and a minimum in those reported by Gross and Jewett. Placing an ectopic testis in the scrotum is a relatively easy procedure, but with those in the canal or abdomen the operation can be extremely difficult. Patience and gentleness are required and it is wise to do one side at a time. Wide retroperitoneal access allows the vessels to be traced to their origin and restricting bands can be more easily visualized and divided. The distance to the scrotum can be shortened by causing the testicle to pass under and inside the deep epigastric vessels so that it emerges at the site of the external ring. If it cannot be brought down without tension the method recommended by Snyder and Chaffin (1955) may be used. The organ is secured at the lowest level possible and six months later a second attempt is made.

The undescended testis since Hunter's day has been regarded as constitutionally defective. Much of the evidence to uphold this view has been based on examination of undescended testes after the age of 5 (in Sohval's series (1954) the ages ranged between 7 months and 78 years). The changes noted might well be due to mal-descent alone. Some support for the view even though it is indirect, can be provided by examining normally descended testes in men with azoospermia and severe oligospermia. In a recent survey of 68 testicular biopsies (Carter, 1956) the following histological changes were observed: germinal aplasia, tubular fibrosis and maturation failure. In 33 (48·5%) the testes were normal in size and consistence, and in only 43 (63·5%) was there a history of infection, injury, hernia operations, and malposition. It is difficult to say what produced these disordered patterns—perhaps primary dysgenesis or some toxic or endocrinological factor, of which we are unaware. It is fair, I think, to assume that similar changes are likely to occur, perhaps more so, in undescended testes so that a certain proportion of cases will be sterile no matter how early and how well the operation has been performed.

*Conclusions.*—(1) As the undescended testes will not develop normally after the age of 5 it seems logical to suggest that they should be in the scrotum before that time. Presumably

the retardation of development, minimal at first, gradually becomes widespread and irreversible. This slow process would account for the results obtained by operation up to the age of 12. Ideally intervention should take place before the age of 5, or as soon as possible afterwards.

(2) A certain number of orchidopexies skilfully performed at the opportune time will fail because of testicular defects. These defects may be due to a primary congenital inadequacy, or to other unknown causes which influence spermatogenesis either before or after operation.

(3) A good cosmetic result after operation is no proof of fertility.

## DISCUSSION

**Mr. Denis Browne** remarked on the advanced age at which Mr. Carver's cases had come to operation, an age at which many males were producing fertile spermatozoa. He suggested that this was because their advisers had "waited to see if they will come down", owing to incapacity to distinguish between true congenital deformities and normal variations in development. The diagnosis was a matter of understanding the anatomy and using the fingers to palpate; he considered hormones were quite useless for this purpose. When the diagnosis was made the rule held, here as elsewhere, that the earlier congenital deformities were corrected the better they developed afterwards. Unfortunately the lack of any agreement on easily demonstrable facts of anatomy made published work on the subject highly misleading.

**Professor Charles Wells** drew attention to the need for further information about the after-history in adult life of patients submitted to bilateral orchidopexy in childhood with particular reference to their success or otherwise in raising families.

**Mr. William S. Mack** said no one really had a clear idea about the question of fertility after orchidopexy since most workers had not followed up the cases that they had done. In addition it was more than likely that there was a difference in the prognosis between the true undescended testicle, which was often an immature organ, and the ectopic testicle, which, anatomically at least, was often well formed and healthy looking. He showed slides illustrating the immature histological picture in an undescended testicle in a boy of 12 as contrasted with the only slightly arrested development of an ectopic testicle in a boy of the same age. He had not yet been able to follow up all his patients but hoped in 10 or 12 years' time to be able to report further on a fairly large series of cases.

In the Fertility Clinic in Glasgow a survey had been made of an eight-year period. During this time 2,433 patients had been examined. 1,096 of them had shown some degree of subfertility. 108 patients in the series had evidence of undescended testicles, some of these patients having had surgical treatment and others having been left alone. Table I shows clearly the very poor outlook as regards fertility of patients with bilateral mal-descent, whether treated by operation or not, but, on reviewing the patients with unilateral descent, it was disconcerting to find that so many of them were sterile and this held good even when the descended testicle felt perfectly normal. In some cases a biopsy had been carried out on the apparently normal testicle and this had revealed a total absence of seminal cells. Obviously in many cases of undescended testicle there was a central fault which affected not merely the fertility of the mal-descended testicle but also the apparently normal descended testicle. In other words, no matter what form of treatment was applied in mal-descent of the testicle a certain fairly high percentage of cases would never become fertile.

TABLE I.

| | | Seminal fluid | | | |
|---|---|---|---|---|---|
| | No. | Normal | Impaired | Grossly impaired | Sperms absent |
| Unilateral. No operation.. | 37 | 7 | 8 | 12 | 10 |
| Unilateral with operation.. | 23 | 4 | 11 | 4 | 4 |
| Bilateral. No operation .. | 21 | 0 | 0 | 5 | 16 |
| Bilateral with operation .. | 27 | 0 | 2 | 3 | 22 |
| Totals | 108 | 11 | 21 | 24 | 52 |

**Mr. Carver,** in reply, said that waiting for undescended testicles to descend might be disappointing, for two reasons.

They might never come down, or if they did they might be non-fertile. Operation should be advised if there is no response to hormone therapy before the age of 5. There seemed to be no place for hormone therapy for unilateral maldescent. Statistics on the fertility of men whose testes descended at puberty were difficult to obtain.

# Bacteriæmia and Septicæmia after Urological Operations

By N. SLADE, M.B., F.R.C.S.
*Bristol*

THE familiar complications of urinary infection such as epididymitis and pyelonephritis are well recognized, and I wish to discuss a much less common but more serious complication—that of septicæmia which occasionally follows urinary sepsis.

Septicæmia, once dreaded in the pre-sulphonamide era, is becoming again more lethal due to the increased incidence of the antibiotic-resistant hospital organism. There has been a change of pattern in the responsible organism since 1937, for example, puerperal streptococcal septicæmia is now rare, on the other hand staphylococcal septicæmia has become relatively more important. The incidence of *B.coli* endocarditis in 1,000 cases of endocarditis analysed by Perry in 1936 was 0·8%, and there are only 4 examples recorded in some 5,000 autopsies performed by the department of Pathology in Bristol during the past twenty years—all 4 cases complicated operations involving the urinary tract.

In the past two years, however, there have been 9 cases of septicæmia diagnosed in our department; 2 of these were staphylococcal and the remainder Gram-negative septicæmias. 3 of these patients died.

The work of Gillespie (1956) on hospital cross-infection in relation to urological cases, has shown that most patients entering hospital with sterile urine acquire infection by cross-infection. The organism is often of the endemic hospital variety resistant to antibiotics and therefore the septicæmia is difficult to treat. In contrast, the patients with acute urinary tract symptoms at the time of admission to hospital are in general those with antibiotic-sensitive organisms (Kirby *et al.*, 1956). These patients, in our experience, do not usually get septicæmia.

In 1929, Scott reported 82 cases of blood-stream infection in urological cases from the Johns Hopkins Hospital, and a year later Barrington and Wright (1930) published their work on "Bacteriæmia following operations on the urethra".

In investigating the cause of "catheter fever" they confirmed that this was due to a bacteriæmia following the passage of instruments or removal of post-operative packs and hæmostatic bags, and that it was limited to cases in which a urinary infection already existed. They obtained positive blood cultures a few minutes after instrumentation and again shortly after the first micturition and concluded that the organisms may gain entrance at the time of trauma and also at the time urine is first passed along the traumatized urethra. The organisms isolated included *B. coli*, *proteus*, *pyocyaneus* and the staphylococcus.

Before I mention the research we have done, and why we did it, I would like to describe some of the 9 cases of septicæmia that have occurred in our department in the last two years. These cases fall into two well-defined groups. In the first there is an acute or subacute urinary infection following instrumentation or operation. This is followed several days later by the classical picture of septicæmia and is well illustrated by the case of Mr. H. J.—1 of 5 cases in the first group.

Mr. H. J., aged 65, a case of multiple bladder papillomata who had previously undergone some dozen cysto-diathermies without complication, was admitted five days after cysto-diathermy with a three-day history of rigors, pyrexia and diarrhœa. Soon after admission jaundice and petechial hæmorrhages were noticed. The urine yielded a heavy *Staph. aureus* infection and a blood culture showed a pure culture of *Staph. aureus*—of the same phage type (42 D.). This patient recovered on tetracycline, but nephrectomy was necessary later because of severe, chronic pyelonephritis.

Another case is that of a young man still in hospital. Reimplantation of the left ureter for stenosis of its lower end was complicated by urinary sepsis, pyelonephritis, ileus, and small bowel obstruction. His clinical condition remained grave with severe toxæmia and a month after his original operation, septicæmia was suspected when petechial hæmorrhages and diarrhœa were noted. A blood culture was taken, and oxytetracycline and later chloramphenicol given by intravenous route. There was a dramatic improvement in the first twenty-four hours and the blood culture yielded a growth of *B. pyocyaneus* with identical organisms in the urine.

In the second group of 4 cases, the illness was of much more rapid onset, bore a constant time relationship to the instrumentation or removal of the post-operative catheter, and had all the characteristics of "bacterial shock".

Our first case was a woman aged 44 who was admitted to our Department with anuria, twenty-four hours after a gynæcological repair operation in which there had been much bleeding. On admission, her general condition was fair; temperature 100° F., blood pressure 125/80. There was no urine in the bladder and the same evening a cystoscopy showed gross œdema of the bladder base and an extra-vesical mass, probably a hæmatoma, was felt between the bladder and vagina. Right ureterostomy was performed. The urine showed a *B. coli* infection and a vaginal swab yielded a coli-

form of the same type. In spite of antibiotics, during the next twelve hours her condition deteriorated rapidly and there was pyrexia of 103° F. The blood pressure dropped to 70/50 although there was no further blood loss. The patient died just forty-eight hours after the first, that is, the gynæcological operation, and autopsy showed obstruction of both lower ureters by the pelvic haematoma. A blood culture taken before death yielded a pure growth of *B. coli* of the same sensitivity pattern as that of the urine.

A very short time after this I was called to the ward to see a patient who had collapsed a few hours after removal of his catheter. He had undergone transurethral resection of multiple papillomata and hypertrophied bladder neck two days previously, and had passed urine just before his collapse with great difficulty and much straining due to partial obstruction with blood clot and debris.

I found him ashen grey, almost unconscious and with a blood pressure of 70/40. As there was some lower abdominal tenderness I thought at first of an extravasation of urine due to a ruptured bladder, also of some catastrophe such as coronary thrombosis or large pulmonary embolus. A little later there were rigors and a pyrexia of 103° F., and because of the similarity to the previous case a blood culture was put up, and parenteral antibiotics given. Intramuscular chloramphenicol and intravenous oxytetracycline were used as the urine specimen of the previous day showed a *B. coli/pyocyaneus* infection. The blood culture the following day yielded a growth of *B. coli* with the same sensitivity pattern and another Gram-negative bacillus which did not subculture. The clinical condition remained grave for twenty-four hours with sustained hypotension, but in three days he had recovered.

Yet a third case occurred a few months later. This followed a retropubic prostatectomy and symptoms commenced three hours after catheter removal. Again a medical emergency was suspected and in this case a medical opinion was sought—the physician suspected massive pulmonary embolism, but in view of our past experiences blood cultures were taken and intramuscular chloramphenicol given. The temperature had by this time risen to 103° F. and the urine showed a proteus infection. There was a dramatic improvement overnight and the following day both culture bottles yielded a pure growth of proteus.

4 cases then presented as "bacterial shock". This condition has received more attention in the United States. In a paper analysing 38 cases Ezzo and Knight (1957) define it as a septicæmia in which there is acute circulatory failure due to liberation of endotoxins, and there must be a positive blood culture and hypotension of 85 mm.Hg systolic or less. 23 cases were due to Gram-negative organisms, and 16 of the 38 cases followed operation on the urinary tract.

We considered that the apparent association of the catheter removal, or first micturition, with the onset of symptoms in the 4 cases of bacterial shock merited clinical investigation. We knew from Barrington's work that a transitory bacteriæmia often followed instrumentation, and it was one step farther to postulate that something similar occurred when withdrawing a catheter along an inflamed mucosal tube in the presence of infected urine.

We have now completed investigation on a total of 50 patients involving some 200 blood cultures. In the first series blood cultures were taken from 19 patients shortly after catheter removal following operations, both open and transurethral, on the prostate and bladder. A control blood culture was taken the following day, and the first urine voided after catheter removal was cultured for organisms. This urine was infected in all cases, although in 14 the pre-operative specimen was sterile.

In the first 9 cases I took the blood sample approximately one hour after catheter removal and these samples remained sterile. The interval was obviously too long and in the remaining 10 cases the blood sample was taken five minutes after catheter removal and in 5 cases we obtained positive blood cultures. The 19 control blood cultures remained sterile.

TABLE I.—1ST SERIES—19 CASES. 5 POSITIVE BLOOD CULTURES

| Case No. | Blood culture | Urine culture |
|---|---|---|
| X | Mixed coliforms | Mixed coliforms |
| XI | *Staph. albus* | *B. coli* |
| | Coag. —ve in 11 days | Proteus |
| XII | *Strep. fæcalis* | *Strep. fæcalis* |
| XIII | *Staph. albus* | Coliforms |
| | Non-hæm. strep. | |
| XVI | *Staph. albus* | Proteus |
| | Coag. —ve | Coliforms |

You will note that in 2 cases the organism isolated in the blood culture was also present in the urine. In 3 cases we were unable to culture similar organisms in the urine, and in 1 of them the blood culture yielded a very scanty growth after eleven days' incubation, and could have been a contaminant. This pilot series showed therefore that a bacteriæmia could occur after catheter removal, and encouraged us to carry out a fully controlled series.

In the second series of 15 patients, we cultured the urine pre-operatively, immediately

before catheter removal, and the first post-catheter micturition specimen. Three blood cultures were taken:

Sample 1. Immediately prior to catheter removal.
Sample 2. Two to three minutes after catheter removal.
Sample 3. Approximately fifteen minutes after catheter removal (Fig. 1).

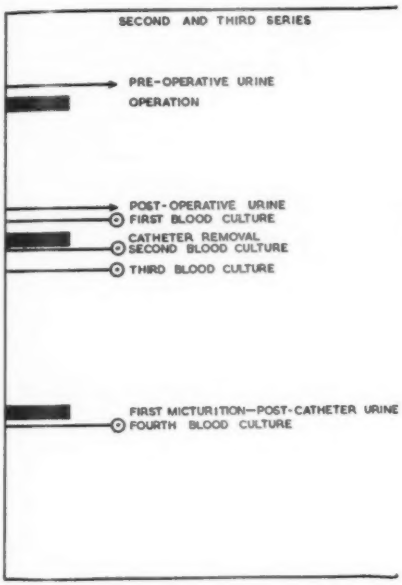

FIG. 1.—Illustrating the time relationships of the various blood cultures and urine samples to the operation and catheter removal.

TABLE II.—2ND SERIES—15 CASES.
4 POSITIVE BLOOD CULTURES

7 Cases—Post-operative Urine Sterile and all Blood Cultures Sterile

| | Case No. | Blood culture | Urine culture |
|---|---|---|---|
| In 8 infected cases | I | Pyocyaneus *Strep. fæcalis* | Pyocyaneus *Strep. fæcalis* |
| | V | *Staph. albus* | *Staph. albus* Coliforms |
| | XIV | *Staph. albus* | *Staph. albus* *Strep. fæcalis* |
| | XII | Atypical Gram-negative bacillus | Atypical Gram-negative bacillus |

In all cases the first and the third blood specimens remained sterile. In 7 cases in which the urine immediately prior to catheter removal was sterile, the second blood culture was sterile, but of the remaining 8 infected cases 3 showed organisms in the blood culture which linked up with those in the urine; and in 1 other case in which the catheter fell out and was replaced shortly after, a blood culture, taken because the patient had a rigor, showed a Gram-negative bacteriæmia corresponding to the urinary infection.

In our third series we took similar urine specimens and blood samples, not only in relation to the catheter removal but, where possible, immediately after the first natural micturition. These latter samples were, for obvious reasons, more difficult to obtain and so far all have remained sterile. Of the 16 cases in the third series, 11 had infected urine at the time of catheter removal, and in only 1 case was there a positive blood culture—two organisms, *Staph. albus* and *Staph. aureus*, were isolated from both blood and urine. The results in the three series are summarized in Table III.

TABLE III.—RESULTS IN 50 CASES

| Urine when catheter removed | No. | Results |
|---|---|---|
| Sterile | 12 cases | All blood cultures were sterile |
| Infected | 38 cases | 28 remained sterile<br>In 10 *cases* positive blood culture 2–10 min. after catheter removal |

We had hoped to demonstrate a bacteriæmia at the first micturition after catheter removal or even after straining to pass urine or straining at stool in the first few hours; so far, however, we have been unsuccessful, but I am convinced that a bacteriæmia can and does occur at this time.

We have also carried out a short series of blood cultures after instrumentation alone — by way of confirming Barrington's work. Table IV shows the result.

TABLE IV.—BLOOD CULTURES AFTER URETHRAL INSTRUMENTATION—11 CASES

| | | |
|---|---|---|
| Urine sterile | 3 cases | All blood cultures sterile |
| Urine infected | 8 cases | Blood cultures positive in 2 cases and similar organism in the urine (*B. coli*, *Strep. fæcalis*) |

## CONCLUSIONS

We have demonstrated that, of 38 patients in whom the urine was infected at the time of catheter removal, a transitory bacteriæmia occurred in 10 and in 7 an organism with the same biochemical and/or sensitivity pattern was found in the urine. The organism appeared a few minutes after catheter removal and disappeared in fifteen minutes.

We believe that this is the mechanism and portal of entry by which a septicæmia can occur after urological operations, and that the incidence may be much greater than is thought because bacterial shock may cause death so rapidly that a confident clinical diagnosis of massive pulmonary embolism is made. However, the unusual combination of hypotension and pyrexia should lead one to think of bacterial shock.

The classical picture of septicæmia may not be clinically distinguished from a severe urinary infection, but the strangely apathetic, pallid, sometimes cyanosed facial appearance in a patient who is known to have pyelonephritis may make one think of a coliform infection.

We have found intravenous oxytetracycline and chloramphenicol the most useful antibiotics, and prompt and energetic therapeutic measures are a matter of profound urgency.

Finally, this is just another reason for improving our methods of prevention of post-operative urinary infection, and our findings give further support to the theory of hæmatogenous origin of the so-called ascending pyelonephritis.

I would like to associate with this work the name of Mr. K. B. Linton, who has done most of the bacteriology. Also I wish to thank Mr. Ashton Miller and Dr. W. A. Gillespie for encouragement and help in preparation of the paper.

## Diabetes Insipidus: The Contribution of Histochemical and Isotope Techniques to the Investigation of Its Pathogenesis

By J. C. SLOPER, M.D.

*London*

THE study of diabetes insipidus has been greatly impeded by the controversy which has persisted, at least until recently, concerning the identity of the cells responsible for the elaboration of the posterior pituitary principles. It is the purpose of this paper briefly to review the evidence which points to the secretion of these substances by neurones, and to consider the implications of this theory in the study of the pathogenesis of diabetes insipidus. Newer cytochemical techniques are proving of great value in the investigation of these problems.

### THE IDENTITY OF THE CELLS SECRETING THE POSTERIOR PITUITARY PRINCIPLES

The secretion of the posterior pituitary principles has been attributed at various times to the interstitial cells of the neurohypophysis, to its nerve-fibres and to its epithelial sheath. In recent years the secretory role of the latter (Fig. 1) has been little supported. Thus,

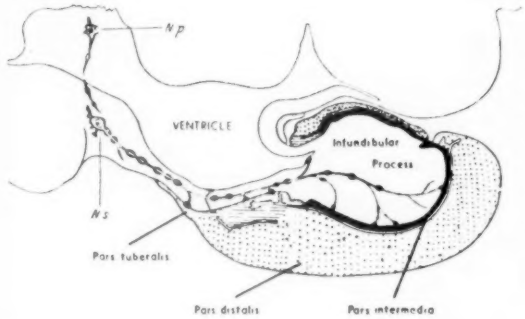

FIG. 1.—Diagram (modified from Bargmann, 1951) of sagittal section through hypothalamus and pituitary of a dog. Note glandular sheath (pars tuberalis and pars intermedia) of neurohypophysis (median eminence: infundibular stem: infundibular process). "Pituicytes" are confined to the neurohypophysis. The main innervation of this region is derived from the supraoptic (N.S.) and paraventricular (N.P.) nuclei, which lie in the hypothalamus.

pharmacological investigations in species which lack a pars intermedia (Geiling and Oldham, 1937) make it unlikely that this is the source of the vasopressor-antidiuretic principle; again, pars tuberalis, which partially ensheathes the infundibular stem (the pituitary stalk) has rarely been attributed with this role (Trendelenburg, 1928; Biggart, 1936). Consequently, if any single structure is the source of the antidiuretic principle, it is probably represented either by the nerves or by the interstitial cells of the neurohypophysis. Direct evidence from tissue cultures is inconclusive (Hild, 1954). The evidence is therefore indirect, and centres on the identification of specific secretory structures in the regions from which posterior pituitary principles can be recovered. As many as five categories of *interstitial* cell can be distinguished with the silver carbonate technique originally recommended by Bucy (1930), namely adeno-, fibro-, reticulo-, and micro-pituicytes (Romeis, 1940), and microglial cells (Vazquez-Lopez, 1942). It is nevertheless held that "pituicytes" thus demonstrated are confined to the neurohypophysis (Weaver and Bucy, 1940), that is, the infundibular process (pars nervosa), infundibular stem (pituitary stalk) and median eminence (the tuber cinereum). It follows that pituicytes cannot be the immediate source of those substances with posterior pituitary activity which have been recovered from the supraoptic and paraventricular nuclear regions of the hypothalamus (Hild and Zetler, 1953).

These nuclear regions contain the cell-bodies of the neurones which innervate the neurohypophysis, cells to which Scharrer and Scharrer (*see* review, 1940), had long attributed an endocrine function. The clue to this function was provided by Gaupp (1944), but it is to Bargmann and his school (*see* review, 1954), that the definitive work in this field must be

attributed. It was shown that a deeply staining chrome-alum hæmatoxyphil (CAH) "neurosecretory" material both filled the infundibular process of the pituitary and extended down into it along the tractus hypophyseus from the supraoptic and paraventricular nuclei. This material was depleted from the pituitary by osmotic stress; it accumulated above lesions in the pituitary stalk; and throughout its distribution substances with posterior pituitary activity could be recovered. It was therefore suggested that hormone and "neurosecretory" colloid were formed in the nuclear regions, passed down the tractus hypophyseus, and were stored and released from the posterior pituitary (Bargmann, 1951; Hild and Zetler, 1951; Bargmann and Scharrer, 1951).

This colloid presented an interesting histochemical problem; for the selectivity with which it could be stained suggested the presence of some substance peculiar to the region, or at least present there in higher concentration than in the neighbouring brain. Schiebler (1951, 1952) supposed that it represented a glyco-lipo-protein bearer-substance for posterior pituitary principle, insisting that the colloid, unlike the active principle, was removed from the unfixed pituitary by lipid-solvents. Like Gersh (*see* Wingstrand, 1953) who had earlier claimed that the Herring bodies of the posterior pituitary were histological artefacts, Schiebler attempted to demonstrate colloid in tissues which had not at any stage of their processing been exposed to formalin. If, however, the pituitary, after lipid-extraction, is fixed in formalin, then colloid can readily be demonstrated. Further, throughout the distribution of Bargmann's CAH "neurosecretory" material there is a substance which reacts far more strongly than the adjacent brain with histochemical techniques for protein-bound cystine (Sloper, 1954, 1955), an amino acid also identified in this region by Barrnett (1954). On histochemical grounds, therefore, it seems likely that there is a protein constituent of "neurosecretory" material, which is present both in hypothalamus and pituitary, and which is rich in cystine. This substance could well represent posterior pituitary principle, particularly if the latter is present in the tissues as a complex of Van Dyke protein and Du Vigneaud's octapeptides (Acher, 1958), since both contain a high proportion of cystine.

In the median eminence and infundibular stem, there is very little "neurosecretory" material and few fibres pass close to capillaries. The opposite is the case in the infundibular process, where the terminal arborizations of the nerves of the tractus hypophyseus ramify in interwoven lobules, ending on the walls of capillaries. The architecture of these lobules has been clarified by Palay (1955, 1957), whose observations amplify those of Romeis (1940), Vazquez-Lopez (1942), and Bodian (1951). From the study of electron-photomicrographs he concluded that "neurosecretory" material is enclosed within nerve fibres and their terminal expansions. These expansions, interdigitating with the processes of pituicytes, which he regards as supportive, end adjacent to capillaries. "Neurosecretory" material he identified with certain vesicles (the granules of Green and Van Breemen, 1955). These are peculiar to the region, and like antidiuretic principle and cystine-rich "neurosecretory" material, are depleted by osmotic stress. The reactivity of the contents of Palay's vesicles with osmium tetroxide does not preclude their protein nature (Bahr, 1954), and it would be of interest to attempt to demonstrate them in electron-photomicrographs with reagents capable of demonstrating the sulphydryl groups of reduced cystine (Bahr and Moberger, 1954).

To summarize, we have to consider some three categories of particle. First, there is the Van Dyke protein, to which, in the tissues, Du Vigneaud's octapeptides may be attached (Acher, 1958). This protein has a molecular weight of 30,000 and probably a diameter of between 0·001 and 0·01 $\mu$. Second, there is Palay's vesicle, which is about 0·1 $\mu$ in diameter and appears in electron-photomicrographs to contain dense, perhaps particulate, inclusions. Third, we have the cystine-rich granule, some 2 $\mu$ in diameter, which is visible with the light microscope. It is possible that protein, particulate inclusion, and granule all represent posterior pituitary principle. It is suggested that the synthesis, transport, storage and release of these particles is the property of the cytoplasm and axoplasm of "neurosecretory" cells (Fig. 2). An obvious compromise between the concepts of central (Bargmann) and peripheral (Bodian) synthesis is to suppose that the entire axoplasm is capable of synthesis, but that transference of posterior pituitary principle into the blood-stream is normally confined to the infundibular process, and perhaps also to the infundibular stem and median eminence.

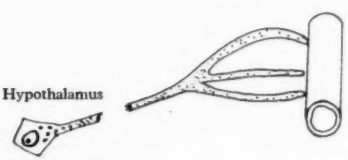

FIG. 2.—Diagram illustrating concept of neurosecretion. Posterior pituitary principle and "neurosecretory" material are held to be formed in the cytoplasm of the cell-bodies of neurones, and perhaps also in their axoplasm; to flow down the axones of these neurones in the tractus hypophyseus; and to be stored in, and released from, the neurohypophysis.

### Pathological Considerations

Necropsies on cases of diabetes insipidus are infrequent and there has been little opportunity to study in such cases the distribution of "neurosecretory" material. The distribution of the latter should, in pathological tissues, be investigated by histochemical techniques rather than by the chrome-hæmatoxylin and aldehyde-fuchsin methods originally introduced for this purpose. Of these techniques, the most convenient depends upon acid-oxidation followed by the use of a basic dye at a very low pH (Adams and Sloper, 1956). This technique allows the differentiation of cystine-rich "neurosecretory" material from those neuronal inclusions which lack such cystine-rich material, but which are nevertheless stained by the chrome-hæmatoxylin and aldehyde-fuchsin methods. The latter, by reason of this lack of specificity, are also of limited value in the investigation of the local changes which follow injury to the pituitary stalk. Histochemical techniques serve here to differentiate cystine-rich material from necrotic debris. Such techniques are also, by reason of their selectivity, of great topographical value. This applies particularly to the identification of the fibres of the tractus hypophyseus. The somewhat devious and caudal course of some of the nerve fibres derived from the paraventricular nuclei has only been recognized since methods were introduced for the demonstration of "neurosecretory" material.

The topographical value of these techniques would alone recommend their use in the investigation of the morbid anatomy of diabetes insipidus. Two varieties of this disease have been recognized, the one primary or idiopathic, the other secondary or symptomatic. The diagnosis of the *idiopathic* form has usually been made on clinical grounds by the exclusion of those conditions which are either known to cause the disease, or are of possible ætiological significance (*see* reviews by Staemmler, 1932; Blotner, 1950; Orthner, 1955; Rodeck, 1955). Pathological information is scanty, and it is not surprising that the proportion of cases included in this idiopathic category has varied greatly. Blotner (1937) provided incomplete pathological data on two such cases, while Gaupp (1941) described in detail the changes in a woman who suffered from the familial form of the disease. Some familial cases are resistant to Pitressin (Forssmann, 1945) and have been termed "nephrogenic"; in such cases the nature of the renal lesion is obscure (Kirman *et al.*, 1956), and I have found no adequate description of the hypothalamo-hypophyseal system.

More is known of the pathology of *symptomatic* diabetes insipidus. The characteristic lesion is a neoplasm or granuloma, interrupting the tractus hypophyseus, and in many instances causing extensive damage to the hypothalamus or pituitary. There are, however, other cases where the extent and nature of the injury are still obscure. For example, in post-encephalitic diabetes insipidus histological damage to hypothalamus and pituitary may be negligible (Croll, 1930; and *see* Orthner, 1955). Again, I have found no description of the pathological changes which occur in cases where the disease has been attributed to psychogenic disturbance, and only one description (Henzi, 1952) of these changes in a case where the condition was due to head injury.

Of these various forms of the disease some examples of symptomatic diabetes insipidus, in which there were destructive lesions interrupting the tractus hypophyseus, have already been investigated with techniques for the demonstration of "neurosecretory" material (Weicksel and Cain, 1952; Drager and Russell, 1954; Rothballer and Dugger, 1955). In every case, a marked diminution of the number of "neurosecretory" cells was observed. The more interesting cases, however, are likely to be those in which little or no damage to the hypothalamo-hypophyseal system has been reported. In such cases, it is possible that the essential lesion lies outside the system, involving for example the paraventricular nuclei of the thalamus, the integrity of which is essential in the dog for the function of the osmoreceptors (Jewell and Verney, 1957). Alternatively, it is possible that the study of the distribution of "neurosecretory" material may reveal cases in which there is a defect in the formation, transport, storage, or release of this material. Some such dysfunction may indeed account for the apparent absence of damage to the nuclear regions in a case of diabetes insipidus recently described by Dingman *et al.* (1957).

### The Pathogenesis of the Disease

The fundamental problem is the reaction of the "neurosecretory" cell to injury. Despite the early and detailed experimental investigations in this field (e.g. Kary, 1924; Mogilnitzky, 1928) the information which has been obtained with conventional histological techniques is limited. The major difficulty is the pseudopathological appearance of the normal "neurosecretory" cell. Not one of such features as gross cytoplasmic vacuolation, the segregation of Nissl substance and nucleus to the periphery of the cell-body, or the loss of Nissl substance, is evidence of irreversible damage (*see* Bargmann, 1954). Moreover, as Tello (1912) stressed, the nerve fibres in the pituitary normally exhibit features indicative elsewhere in the nervous system of regeneration and degeneration, features which in terms of the "neurosecretory" hypothesis merely indicate the distortion of nerve terminals by "neurosecretory" material.

attributed. It was shown that a deeply staining chrome-alum hæmatoxyphil (CAH) "neurosecretory" material both filled the infundibular process of the pituitary and extended down into it along the tractus hypophyseus from the supraoptic and paraventricular nuclei. This material was depleted from the pituitary by osmotic stress; it accumulated above lesions in the pituitary stalk; and throughout its distribution substances with posterior pituitary activity could be recovered. It was therefore suggested that hormone and "neurosecretory" colloid were formed in the nuclear regions, passed down the tractus hypophyseus, and were stored and released from the posterior pituitary (Bargmann, 1951; Hild and Zetler, 1951; Bargmann and Scharrer, 1951).

This colloid presented an interesting histochemical problem; for the selectivity with which it could be stained suggested the presence of some substance peculiar to the region, or at least present there in higher concentration than in the neighbouring brain. Schiebler (1951, 1952) supposed that it represented a glyco-lipo-protein bearer-substance for posterior pituitary principle, insisting that the colloid, unlike the active principle, was removed from the unfixed pituitary by lipid-solvents. Like Gersh (*see* Wingstrand, 1953) who had earlier claimed that the Herring bodies of the posterior pituitary were histological artefacts, Schiebler attempted to demonstrate colloid in tissues which had not at any stage of their processing been exposed to formalin. If, however, the pituitary, after lipid-extraction, is fixed in formalin, then colloid can readily be demonstrated. Further, throughout the distribution of Bargmann's CAH "neurosecretory" material there is a substance which reacts far more strongly than the adjacent brain with histochemical techniques for protein-bound cystine (Sloper, 1954, 1955), an amino acid also identified in this region by Barrnett (1954). On histochemical grounds, therefore, it seems likely that there is a protein constituent of "neurosecretory" material, which is present both in hypothalamus and pituitary, and which is rich in cystine. This substance could well represent posterior pituitary principle, particularly if the latter is present in the tissues as a complex of Van Dyke protein and Du Vigneaud's octapeptides (Acher, 1958), since both contain a high proportion of cystine.

In the median eminence and infundibular stem, there is very little "neurosecretory" material and few fibres pass close to capillaries. The opposite is the case in the infundibular process, where the terminal arborizations of the nerves of the tractus hypophyseus ramify in interwoven lobules, ending on the walls of capillaries. The architecture of these lobules has been clarified by Palay (1955, 1957), whose observations amplify those of Romeis (1940), Vazquez-Lopez (1942), and Bodian (1951). From the study of electron-photomicrographs he concluded that "neurosecretory" material is enclosed within nerve fibres and their terminal expansions. These expansions, interdigitating with the processes of pituicytes, which he regards as supportive, end adjacent to capillaries. "Neurosecretory" material he identified with certain vesicles (the granules of Green and Van Breemen, 1955). These are peculiar to the region, and like antidiuretic principle and cystine-rich "neurosecretory" material, are depleted by osmotic stress. The reactivity of the contents of Palay's vesicles with osmium tetroxide does not preclude their protein nature (Bahr, 1954), and it would be of interest to attempt to demonstrate them in electron-photomicrographs with reagents capable of demonstrating the sulphydryl groups of reduced cystine (Bahr and Moberger, 1954).

To summarize, we have to consider some three categories of particle. First, there is the Van Dyke protein, to which, in the tissues, Du Vigneaud's octapeptides may be attached (Acher, 1958). This protein has a molecular weight of 30,000 and probably a diameter of between 0·001 and 0·01 $\mu$. Second, there is Palay's vesicle, which is about 0·1 $\mu$ in diameter and appears in electron-photomicrographs to contain dense, perhaps particulate, inclusions. Third, we have the cystine-rich granule, some 2 $\mu$ in diameter, which is visible with the light microscope. It is possible that protein, particulate inclusion, and granule all represent posterior pituitary principle. It is suggested that the synthesis, transport, storage and release of these particles is the property of the cytoplasm and axoplasm of "neurosecretory" cells (Fig. 2). An obvious compromise between the concepts of central (Bargmann) and peripheral (Bodian) synthesis is to suppose that the entire axoplasm is capable of synthesis, but that transference of posterior pituitary principle into the blood-stream is normally confined to the infundibular process, and perhaps also to the infundibular stem and median eminence.

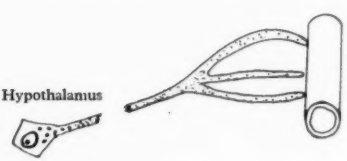

FIG. 2.—Diagram illustrating concept of neurosecretion. Posterior pituitary principle and "neurosecretory" material are held to be formed in the cytoplasm of the cell-bodies of neurones, and perhaps also in their axoplasm; to flow down the axones of these neurones in the tractus hypophyseus; and to be stored in, and released from, the neurohypophysis.

### Pathological Considerations

Necropsies on cases of diabetes insipidus are infrequent and there has been little opportunity to study in such cases the distribution of "neurosecretory" material. The distribution of the latter should, in pathological tissues, be investigated by histochemical techniques rather than by the chrome-hæmatoxylin and aldehyde-fuchsin methods originally introduced for this purpose. Of these techniques, the most convenient depends upon acid-oxidation followed by the use of a basic dye at a very low pH (Adams and Sloper, 1956). This technique allows the differentiation of cystine-rich "neurosecretory" material from those neuronal inclusions which lack such cystine-rich material, but which are nevertheless stained by the chrome-hæmatoxylin and aldehyde-fuchsin methods. The latter, by reason of this lack of specificity, are also of limited value in the investigation of the local changes which follow injury to the pituitary stalk. Histochemical techniques serve here to differentiate cystine-rich material from necrotic debris. Such techniques are also, by reason of their selectivity, of great topographical value. This applies particularly to the identification of the fibres of the tractus hypophyseus. The somewhat devious and caudal course of some of the nerve fibres derived from the paraventricular nuclei has only been recognized since methods were introduced for the demonstration of "neurosecretory" material.

The topographical value of these techniques would alone recommend their use in the investigation of the morbid anatomy of diabetes insipidus. Two varieties of this disease have been recognized, the one primary or idiopathic, the other secondary or symptomatic. The diagnosis of the *idiopathic* form has usually been made on clinical grounds by the exclusion of those conditions which are either known to cause the disease, or are of possible ætiological significance (*see* reviews by Staemmler, 1932; Blotner, 1950; Orthner, 1955; Rodeck, 1955). Pathological information is scanty, and it is not surprising that the proportion of cases included in this idiopathic category has varied greatly. Blotner (1937) provided incomplete pathological data on two such cases, while Gaupp (1941) described in detail the changes in a woman who suffered from the familial form of the disease. Some familial cases are resistant to Pitressin (Forssmann, 1945) and have been termed "nephrogenic"; in such cases the nature of the renal lesion is obscure (Kirman *et al.*, 1956), and I have found no adequate description of the hypothalamo-hypophyseal system.

More is known of the pathology of *symptomatic* diabetes insipidus. The characteristic lesion is a neoplasm or granuloma, interrupting the tractus hypophyseus, and in many instances causing extensive damage to the hypothalamus or pituitary. There are, however, other cases where the extent and nature of the injury are still obscure. For example, in post-encephalitic diabetes insipidus histological damage to hypothalamus and pituitary may be negligible (Croll, 1930; and *see* Orthner, 1955). Again, I have found no description of the pathological changes which occur in cases where the disease has been attributed to psychogenic disturbance, and only one description (Henzi, 1952) of these changes in a case where the condition was due to head injury.

Of these various forms of the disease some examples of symptomatic diabetes insipidus, in which there were destructive lesions interrupting the tractus hypophyseus, have already been investigated with techniques for the demonstration of "neurosecretory" material (Weicksel and Cain, 1952; Drager and Russell, 1954; Rothballer and Dugger, 1955). In every case, a marked diminution of the number of "neurosecretory" cells was observed. The more interesting cases, however, are likely to be those in which little or no damage to the hypothalamo-hypophyseal system has been reported. In such cases, it is possible that the essential lesion lies outside the system, involving for example the paraventricular nuclei of the thalamus, the integrity of which is essential in the dog for the function of the osmoreceptors (Jewell and Verney, 1957). Alternatively, it is possible that the study of the distribution of "neurosecretory" material may reveal cases in which there is a defect in the formation, transport, storage, or release of this material. Some such dysfunction may indeed account for the apparent absence of damage to the nuclear regions in a case of diabetes insipidus recently described by Dingman *et al.* (1957).

### The Pathogenesis of the Disease

The fundamental problem is the reaction of the "neurosecretory" cell to injury. Despite the early and detailed experimental investigations in this field (e.g. Kary, 1924; Mogilnitzky, 1928) the information which has been obtained with conventional histological techniques is limited. The major difficulty is the pseudopathological appearance of the normal "neurosecretory" cell. Not one of such features as gross cytoplasmic vacuolation, the segregation of Nissl substance and nucleus to the periphery of the cell-body, or the loss of Nissl substance, is evidence of irreversible damage (*see* Bargmann, 1954). Moreover, as Tello (1912) stressed, the nerve fibres in the pituitary normally exhibit features indicative elsewhere in the nervous system of regeneration and degeneration, features which in terms of the "neurosecretory" hypothesis merely indicate the distortion of nerve terminals by "neurosecretory" material.

Unequivocal evidence of degeneration, that is degeneration characterized by cytolysis, karyorrhexis and karyolysis, does not, in fact, appear in the human until between seventeen and forty-two days after injury to the pituitary stalk. To investigate the susceptibility of the "neurosecretory" cell to various forms of injury it would clearly be advantageous to have histological criteria indicative of irreversible damage at an earlier stage. A change which can be interpreted in this way is the retrograde accumulation of "neurosecretory" material in the axone and the cell-body of many "neurosecretory" cells following, for example, hypophysectomy in the rat (Stutinsky, 1951). In a human, where death had occurred ten days after hypophysectomy for the relief of malignant disease, such changes were very marked (Sloper and Adams, 1956), and it seems that at least a proportion of the neurones thus affected were undergoing irreversible degeneration. This interpretation must nevertheless be made with caution, for conspicuous aggregations of "neurosecretory" material have been observed in the intrahypothalamic portion of the tractus hypophyseus in the overhydrated dog (Andersson and Jewell, 1957). In such animals the accumulation could be a reversible change, indicative of a transient disturbance of the axonal transport of the "neurosecretory" material.

Early pathological changes in "neurosecretory" cells can be further investigated in two ways, the first involving the study of those enzymes which are conspicuous in the cytoplasm of the neurones of the supraoptic and paraventricular nuclei. These include acid phosphatase and various esterases (Eränkö, 1951; Gomori and Chessick, 1953; Sloper, 1955). Their function is unknown, but it has been shown that certain esterases are markedly affected by osmotic stress (Pepler and Pearse, 1957). A property of the "neurosecretory" cell which is easier to measure is its uptake of the isotope sulphur 35, injected intracisternally in the form of labelled cysteine (Arnott and Sloper, 1958). Sulphur 35 accumulates first in the nuclear region, and later in the infundibular process. We are hoping to use this property of the hypothalamo-hypophyseal system as a means of studying its susceptibility to injury, and in particular to injury by ionizing radiations (Arnold, 1955).

A second problem under investigation is the late effect of injury on the "neurosecretory" cell. Shortly after section of the pituitary stalk there is a local accumulation of CAH material, which, like that in the nerve fibres, is rich in cystine. This phenomenon has been observed in many species including man. In the rat the accumulation appears either to persist or to reform, and a month after the injury the median eminence, now full of "neurosecretory" material, resembles the normal posterior pituitary (Stutinsky, 1951). The histochemical properties of these persistent accumulations have yet to be investigated. Such accumulations are not depleted by osmotic stress quite as readily as the "neurosecretory" material stored in the normal infundibular process (Billenstien and Leveque, 1955). Their development can be explained in two ways. Fibres normally ending in the median eminence may take over the function of fibres destroyed by section of the pituitary stalk. Alternatively, injured fibres may be capable of regeneration, and of making contact with vessels in the median eminence. These alternatives have also to be considered in the interpretation of the changes which occur in the human median eminence following surgical injury (Sloper and Adams, 1956). In particular, the possibility of neuronal regeneration should not be dismissed (Tello, 1912; Bodian and Maren, 1951; Diepen *et al.*, 1954) despite the fact that regeneration is held not to occur in the central nervous system. If substantiated it would explain a phenomenon stressed by many workers (*see* Porter and Miller, 1948), namely the spontaneous recovery of many cases of traumatic diabetes insipidus.

## Conclusion

An account has been given of recent investigations into the pathogenesis of diabetes insipidus. These have been based on the hypothesis—still disputed, although no attempt has been made here to discuss its more controversial aspects—that antidiuretic hormone is formed not by "pituicytes" but by certain secretory neurones of the hypothalamo-neurohypophyseal system. It follows from this hypothesis that the essential abnormality in diabetes insipidus is the destruction or dysfunction of these neurones, and it is with their reaction to stress and to injury that we have been concerned. An outline has been given of the application of certain newer histochemical techniques to their investigation both in the experimental animal and in human material. Since few cases of diabetes insipidus come to necropsy, and since our understanding of its patholgy is still incomplete, it would be of the greatest value if material from such cases could be investigated by the techniques now available.

## The Application of Histochemical Methods for Protein Identification in the Study of Certain Pathological Problems

By C. W. M. ADAMS, M.B., B.Ch.
*London*

THE histochemical methods of identifying proteins fall into two classes. The first group comprises those methods which depend on the characteristics of a protein as a whole, such as solubility tests, determination of iso-electric point, reactions and stains for free amino groups and localization by labelled antibodies. The other type of method relies upon the recognition of individual amino acids in protein by specific colour-reactions. It is with these colour-reactions and their application to pathology that this paper is concerned.

These specific reactions depend upon some individual chemical feature of the amino acid concerned, such as the disulphide group of cystine or the 3-indole configuration of trypto-

phane. For this reason it is unlikely that any histochemical colour-tests will ever be devised for the simpler amino acids, such as glycine and alanine, which do not have such characteristic chemical features.

At present the amino acids which can be demonstrated by reliable histochemical methods are: cysteine, cystine, tryptophane, tyrosine and arginine. The chemical reactions involved in some of these methods are still unknown even though, in practice, these methods are quite specific. In this category are the Millon method for the phenolic group of tyrosine and the Sakaguchi method for the guanidinyl group of arginine.

In contrast to these older arbitrary methods, Danielli (1947) has introduced a method for the simultaneous demonstration of tyrosine, tryptophane and histidine. This method relies on exact biochemical principles, namely the combination of these amino acids, in an alkaline medium, with one pole of a tetrazonium compound. In a second stage the diazo group at the opposite pole is coupled with a chromogenic substance to provide sufficient colour for microscopy. The colour developed is, in fact, strong and well defined and this is a most useful method for the general recognition of protein. It has been claimed by Landing and Hall (1956) that a sixth amino acid, histidine, may be stained by a modification of this tetrazonium technique. These authors stated that, after iodine blockade, the staining of the reactive groups of tyrosine and tryptophane was suppressed leaving only histidine to react.

In contrast to the use of diazonium compounds as coupling agents for protein, Lillie (1957) has introduced a method for the direct diazotization of tissue proteins. This application of Morel and Sisley's protein diazotization method is claimed to be a histochemical test for tyrosine. However, the method may not be very specific, for there is evidence (Fraenkel-Conrat, 1951) that tryptophane may also undergo diazotization or nitrosylation with nitrous acid and then combine with aromatic amines and phenols in the same way as diazotized tyrosine (Eagle, 1936).

Cystine and cysteine can be stained by methods which also lend themselves to critical evaluation. The methods for cystine in current use may be classified as either reduction or oxidation techniques. With the reduction methods cystine is converted wholly or in part to cysteine by suitable reducing agents (Barrnett and Seligman, 1954) or by alkaline hydrolysis (Pearse, 1953). In a second stage, the sulphydryl group of the newly-formed cysteine reduces a suitable redox-indicator or sulphydryl-reagent to a coloured product. Certain mercurial compounds and organic halogens can be used to blockade the sulphydryl group and thus confirm the specificity of the test.

The oxidation methods for cystine depend upon the initial oxidation of the disulphide group of cystine to sulphonate. This sulphonate group, which is a highly-ionized acid-radicle, may be linked to certain basic dyes. Now, if the dye is dissolved in strong acid (pH 0·2), the dissociation of all other "tissue" acid-radicles is suppressed, except sulphate and the sulphonate radicle of oxidized cystine. In practice sulphate can be excluded by treating an unoxidized section with the dye alone. It follows that staining seen only in the oxidized section is due to cystine (or cysteine).

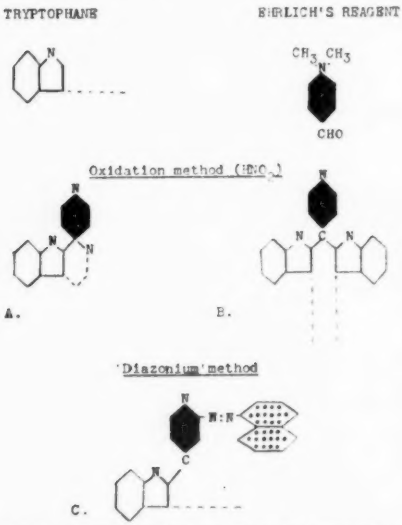

FIG. 1.—Histochemical reactions for tryptophane.

Recently several new histochemical methods have been described for the detection of tryptophane and related indoles. The methods which give the strongest results and which also are the easiest to use depend upon the reaction of tryptophane with Ehrlich's reagent, p-dimethylaminobenzaldehyde. In the simplest of these tryptophane is first condensed with the reagent, after which the resulting compound is oxidized by nitrous acid to a deep blue pigment (Adams, 1957; Glenner, 1957).

It is possible that the blue pigment is a derivative of β-carboline (Fig. 1A) but Glenner has advanced an alternative view that the pigment is Emil Fischer's rosindole compound (Fig. 1B). It is improbable, however, that rosindole is formed since the molecules of tryptophane in a protein would seldom be sufficiently close together to enable two of them, simultaneously, to combine with a molecule of Ehrlich's reagent. Moreover it has been shown

(Giral and Laguna, 1950; Portner and Högl, 1953) that these blue pigments are not formed from indole, the parent substance of tryptophane. This would be difficult to explain by the "rosindole hypothesis", where the side-chain in the "3" position takes no part in the reaction. On the other hand, to form a carboline the side-chain at the "3" position would be essential in order to complete the third ring: carbolines are not formed when the side-chain is either absent or at the "2" position. However, against the "carboline hypothesis", it must be stated that blue pigments are formed *in vitro* from those 3-indolyl derivatives which have insufficient carbon atoms in their side-chain to complete a third ring.

In contrast to these oxidation methods, Glenner and Lillie (1957) have introduced another method for tryptophane, that of coupling a diazonium compound with the indole-Ehrlich compound (Fig. 1c). It is claimed that this reaction takes place at the ortho-position of Ehrlich's reagent although these authors did not exclude coupling with the indole nucleus at the "1" position (Bruemmer *et al.*, 1957).

### Application to Pathological and Experimental Material

These histochemical methods for amino acids may be used to identify the anatomical site of specific proteins known, by biochemical analysis, to be rich in a particular amino acid. Further, the protein in question may then be studied in a semi-quantitative way in both pathological and experimental conditions. To illustrate the application of these methods I propose to refer briefly to some proteins, polypeptides or derivatives of amino acids, where there are unusually high proportions of either cystine or tryptophane (*see* Table I).

Table I.—Amino Acids in Proteins or Tissues (Compiled from various sources)

| Protein or tissue | Approximate content of Cystine % | Tryptophane % | Tyrosine % |
|---|---|---|---|
| Posterior pituitary hormones | 18–19 | 0 | 13 |
| carrier | 17–18 | 0 | 3·4 |
| Li-Sayers protein | 8 | ? | ? |
| Melanophore-stimulating hormone | 0 | 10 | 9 |
| Serotonin | — | equiv. to 100 | — |
| Neurokeratin | 4·3 | 1·8 | 4·9 |
| Pepsin | 1·5 | 2·3 | 10·5 |
| Trypsin | ? | 4·6 | ? |
| Trypsinogen | ? | 2·9 | ? |
| Chymotrypsinogen | 4·5 | 5·4 | 2·9 |
| Liver proteins | 1·4 | 1·6 | 4·1 |
| Muscle proteins | 1·1 | 1·2 | 3·1 |
| Epidermis | 3·0 | 1·8 | 13·9 |
| Hair keratin | 15·9 | 1·3 | 3·0 |

### Neurosecretory Material

The neurosecretory material of the neurohypophyseal system is stained strongly by an oxidation method for cystine (Adams and Sloper, 1956) and in some species by reduction methods as well (Barrnett, 1954; Sloper, 1954, 1955; Howe and Pearse, 1956). This observation is not unexpected since the posterior pituitary hormones and their carrier-protein contain more cystine than any other protein or peptide as yet isolated. Accordingly, it is reasonable to infer that the stainable material contains the active hormones or the carrier or, possibly, both. However, it is likely that the histochemical and staining properties of neurosecretory material are due to the carrier. This may be deduced from the negative reaction of the material for tyrosine, a finding which is more consistent with the small fraction of tyrosine in the carrier than with the high proportion of this amino acid in the active hormones (*see* Table I).

### Crooke-Russell Cell

Certain pituitary basophils, including the Crooke-Russell cell, contain muco-protein granules rich in cystine. The granules of these cells were stained blue by an oxidation method for cystine (performic acid-alcian blue) while the granules of the other basophil, containing little cystine, were stained red by PAS (Adams and Swettenham, 1958). This method is a development of the performic acid-aldehyde-fuchsin technique used by Russell (1956) for distinguishing beta and delta basophils in the human pituitary.

There is only one protein or hormone, as yet isolated from the adenohypophysis, which contains such a characteristic amount of cystine: this is the protein which was isolated by Li, Evans and Simpson and by Sayers *et al.* in 1943 (*see* Table I). This Li-Sayers protein was thought at first to be ACTH, but this claim was later shown to be wrong (Astwood, *et al.*, 1952). Meanwhile, Sayers (1952) has suggested that the protein may be a carrier for ACTH. Our observations on the basophils in Addison's disease at least support the opinion that the protein is related to the formation of ACTH.

### Melanophore-stimulating Hormone

Extracts of the pars intermedia of lower mammals and vertebrates have an expanding action on the melanophores of the frog dermis. The hormone responsible for this effect is now known to be a polypeptide containing about 10% of tryptophane (Harris and Ross, 1956). When the corresponding histochemical test for tryptophane was applied to the frog pituitary fine blue granules were seen in the basophils of the pars intermedia. It has not yet been possible, however, to determine by experimental means whether these granules are, in fact, the active melanophore-expanding hormone.

### Serotonin (5-Hydroxytryptamine)

Since serotonin is a derivative of tryptophane, a strong reaction with the carboline method might be expected in the argentaffin granules of the alimentary tract and carcinoid tumours. In practice argentaffin granules could not be identified by this method. The failure here was possibly a result of formalin fixation, for formaldehyde could prevent the reaction by combining with serotonin in the same way as does Ehrlich's reagent. The difficulty arises, as reported by Barter and Pearse (1953), that the granules cannot be seen unless formalin fixation is used. However, in an alcohol-fixed carcinoid tumour a fairly strong reaction was found in the peripheral cells of the trabeculæ, the site of the argentaffin granules in the formalin-fixed blocks of the same tumour. Nevertheless, as with the melanophore-stimulating hormone, it does not follow that the stained material was the active hormone, for any of the precursors of serotonin, such as 5-hydroxytryptophane or even tryptophane, could also have given a positive reaction.

### Neurokeratin

In contrast to the secretory proteins the next example is a structural protein of the nervous system. Neurokeratin was first isolated as a soda-insoluble substance from the brain by Ewald and Kühne (1877), but little was known about the nature of "neurokeratin" proteins until the recent work of Folch and Lees (1951) and LeBaron and Folch (1956). Some distinguishing features of these proteins are that they are resistant to digestion by trypsin, pepsin and papain and that they contain about 1·8% of tryptophane. These features lend themselves to the anatomical localization of the neurokeratins, for when sections of alcohol-fixed brain and peripheral nerve were digested in trypsin and stained for tryptophane only the myelin sheath was still seen. The proteins of the ground substance and glial fibres had disappeared while a considerable part of the myelin protein was undigested. This suggests that the neurokeratins are derived from the myelin sheath, probably from the protein layers which have been described in myelin lamellæ by Fernández-Morán (1950) and Finean (1953).

During Wallerian degeneration of the peripheral nerve, at the early stage before the lipids are chemically degraded (Johnson *et al.*, 1950), the myelin lipids appeared to be dissociated physically from the neurokeratin or protein material. It is likely, therefore, that this dissociation of lipid from protein is an important factor in demyelination since it occurs before the stage of chemical degradation of myelin. We have not yet established, however, whether this type of dissociation also occurs during demyelination in the C.N.S.

### Experimental Protein Malnutrition

As part of an investigation on protein malnutrition in experimental animals (Adams *et al.*, 1958) a low protein/high carbohydrate diet (cassava) was fed to rats and mice and a study was made of the effect of this deficiency on the proteins of zymogen, liver and muscle. The intense reaction for tryptophane found in pancreatic, submandibular ("serous tubular"), peptic and Paneth cell zymogen of normal animals was probably due to the presence of tryptophane-rich proteolytic enzymes (*see* Table I). The number of zymogen granules in these secretory cells decreased quite early in the course of protein malnutrition. This was associated in the pancreas with atrophy of acini and in the submandibular gland with marked shrinkage of the zymogenic "serous tubules". At the same time there was considerable loss of cytoplasmic protein from the liver but no comparable loss of protein from muscle (tryptophane) or from the epidermis (cystine, tyrosine and arginine).

Davies (1948, 1952) has suggested that the pancreatic changes are the essential feature of kwashiorkor, a disease of tropical children nourished on low protein/high carbohydrate diets. He regarded the atrophy and degranulation of pancreatic acini as more fundamental than the fatty change in the liver.

However, in our experimental animals, fed on a diet of cassava, both the pancreas and the liver were affected simultaneously as regards loss of protein. Furthermore, the protein-loss from the liver bore no relationship to the degree of fatty change found. It is likely, if the experimental animal can be compared with the human, that the same may apply in kwashiorkor. Sprinson and Rittenberg (1949) have found that the turnover of labelled protein in the liver is about 3½ to 15 times as rapid, depending upon the species, as that of protein in

muscle and skin. This may account for the considerable loss of protein from liver when compared with our failure to detect a loss from skin and muscle.

Clearly there is much scope for the use of histochemical protein methods in experimental pathology.

# Some Histochemical Aspects of Pædiatric Pathology, with Remarks on Quantitation in Histochemistry

By IRVINE J. HUNTER, M.B., B.Sc.

*Research Fellow in Histochemistry, The Hospital for Sick Children, London*

HISTOCHEMICAL techniques such as micro-incineration, X-ray diffraction and autoradiography are specialised tools of research, and rather far removed from classical morbid anatomy, as, for that matter, is the morphological world of the electron microscopist. On the other hand, that part of the general field of histochemistry which may be designated "histochemical staining" can be regarded as an extension and expansion of classical morbid anatomy by other or more refined techniques. Indeed, some histochemical techniques, such as the periodic-acid-Schiff method (Hotchkiss, 1948; McManus, 1946, 1948*a*, *b*), have been incorporated into the normal armamentarium of morphological diagnosis. (Originally suggested as a histological method it was later accepted as a histochemical method (*see* Pearse, 1953), and has been received into histology in its histochemical setting.)

I wish briefly to consider the interrelation of histochemical staining and allied procedures with morphological histopathology, using a few diseases of childhood merely as examples, and to conclude with some remarks on the question of quantitation in the field of histochemical staining.

Histochemical techniques may be used as an adjunct to histopathological diagnosis, as in the demonstration of motor end-plates of muscle by their acetyl-cholinesterase activity (see Woolf and Till, 1955). In a few instances the diagnosis may fall largely on the histochemist, for example in the condition of hypophosphatasia, first described by Rathbun

(1948), which clinically has some resemblance to rickets. In this condition impaired osteogenesis, apparently primary (Fraser *et al.*, 1955), often leading to craniostenosis, is associated with deficient alkaline phosphatase in the bones (*see* Schlesinger *et al.*, 1955; Fraser, 1957). Since in some cases the blood alkaline phosphatase may be within normal limits, the definitive diagnosis may depend on chemical and histochemical demonstration of grossly lowered alkaline phosphatase activity in a bone biopsy. An article in "Recent Advances in Clinical Pathology" gives details of the applicability of histochemical methods to general diagnostic histology. This was written by the late George Gomori, whose sudden and untimely death earlier this year was indeed a bitter blow to the science of histochemistry.[1]

Turning to the application of histochemistry in the investigation of problems of disease—the histochemist usually begins with a problem which appears incapable of solution by the means at the disposal of classical morbid anatomy. After the chemical phase of the procedure is over there comes the histological. Under the microscope, the result must be analysed from both the chemical and morphological points of view, so that a sound knowledge of morphology is essential for the interpretation of the results of histochemical (and, one might venture to add, of experimental) research in pathology.

Dr. C. W. M. Adams has illustrated ways of staining proteins by means of the demonstration of specific groups in particular amino acids, the best known of these methods being the classical reaction of Millon (1849), modified by subsequent workers such as Bensley and Gersh (1933), which demonstrates the phenolic group of tyrosine. I should like to illustrate the other major type of reaction used histochemically to demonstrate protein, namely staining with acidic dyes in acid solution. Every histologist knows that "eosinophil" is an equivalent of "acidophil"; these methods are thus fundamentally the familiar eosin-staining of the cytoplasm in a different guise, using more precise stains under more controlled conditions. The principles of staining by acid and basic dyes were considered by Singer (1952).

The acidophilic properties of proteins depend in practice upon three chemical groupings—the guanidinyl group of arginine, the epsilon-amino group of lysine, and the imidazyl group of histidine.[2] At acid pH, the coloured anion of acid dyes will combine with these basic groups and stain the protein. In comparison with the methods which demonstrate specifically groupings in particular amino acids these methods are not, to the same extent, chemically specific for proteins, but are convenient for their demonstration, especially for the histone of the nucleus, which, because it is more basic than the cytoplasmic proteins, can be differentially stained by using a solution with a lesser concentration of hydrogen ions. The principle is similar to the use of solutions of greater hydrogen-ion concentration for differential staining by basic dyes, of basophilic substances, a procedure made use of in the well-known methylene-blue extinction test introduced by Pischinger (1926, 1927*a*, *b*), and used particularly by Dempsey and Singer (1946), and their co-workers (Dempsey *et al.*, 1947; Singer and Morison, 1948; Dempsey *et al.*, 1950).

The staining of protein by naphthol yellow S in acid solution was described by Deitch (1955). Similar results can be obtained with the better-known chemically related stain, Martius yellow.[3] In a section of tongue it is apparent that everything is stained a deep yellow except the mucus-secretion in the glandular cells. (The author showed a number of photomicrographs taken from children with fibrocystic disease of the pancreas.)

At this point we may make a diversion to consider a histochemical trichrome staining method described by Himes and Moriber (1956). Azure A is one of the stains which are formed as a result of the polychroming of methylene-blue (*see* Conn, 1953). The work of Kramer and Windrum (1955) has shown that azure A is to be preferred to thionine, and is more rational than toluidine blue, for the demonstration of metachromasia of mucin. It has, however, other uses: it can be used as a basic dye, to stain nucleic acids in general (being so used by Pollister, 1950); and after Feulgen hydrolysis of the section with hydrochloric acid it acts, in acid metabisulphite solution, as a specific nuclear stain. This leaves leucofuchsin for use in the periodic-acid-Schiff reaction, and finally protein can be stained with naphthol yellow S. The yellow goes into the nuclei, converting the blue of the azure A to green. The result with this method differs from the histological trichrome methods, such as iron hæmatoxylin, van Gieson and Masson's stain, in that collagen and muscle are not differentially stained. Its purpose is, of course, quite different—to show, not general structure, but distribution of chemical substances.

[1]Born in 1904 at Budapest; died on February 28, 1957. In the original Hungarian his name was Gömöri, pronounced "Gúmmery", but the anglicized version is established by usage, and, in this instance, is justified by the fact that his adopted country was the United States of America. A short account of his career (Lillie, 1957) was published in *The Journal of Histochemistry and Cytochemistry*.

[2]Almost all alpha-amino groups in proteins are, of course, occupied in peptide linkages, but a small fraction of the basic properties may be due to the few terminal alpha-amino groups.

[3]Naphthol yellow S is the dipotassium salt of flavianic acid. Martius yellow (sometimes known as naphthol yellow) is the salt of an acid which lacks the sulphonic acid group present in flavianic acid.

Another dye that may be used for the staining of proteins is fast green F.C.F., which is of interest as the dye which first focused attention on the anionic staining of proteins as a histochemical procedure, when it was utilized for this purpose by Schrader and Leuchtenberger (1950).[1] A section of ileal mucosa from a case of meconium ileus, stained by fast green at a very acid pH (about 1·5), shows that everything, including the glandular mucin, is stained green at this pH, the red blood corpuscles and the more condensed material of the intestinal contents staining in a much deeper shade. When hyaline cartilage is stained with basic dyes and basic dye lakes the nucleic acid of the nucleus and the acid mucopolysaccharide of the matrix are stained, whereas here a similar histological effect is obtained by staining the protein in these two structures.

So far we have been considering the demonstration of features which may not be apparent by classical morphological staining. However, on occasions histochemical methods may be used to demonstrate as well as, if not better than, the usual impregnation or staining methods, the structural niceties of classical morphology. Fig. 1 is tongue muscle, stained by fast green, showing quite clearly not only the Q band (light) and J band (dark), but also the Z line (light) in the J band and the M line (dark) in the Q band. The result is thus the opposite of that obtained with basic dyes and dye lakes, such as iron hæmatoxylin, and similar to that seen with silver impregnation and polarized light, the isotropic segments being stained more deeply. The staining of the cross striations of muscle by acid and basic dyes was investigated by Dempsey *et al.* (1946), using orange G as their acid dye.

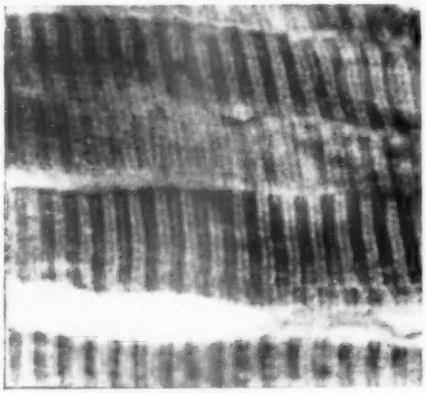

FIG. 1.—Tongue muscle from a child aged 9 months, showing the cross striations. ×2,000. Stained by fast green F.C.F. at approximately pH 3·0, M/5 acetate buffer. The isotropic segments are deeply stained.

Thirdly, the use of histochemical methods may bring to light morphological problems which were not apparent before. Consider the obstructed segment in a case of meconium ileus, a condition thought to be, at least in the great majority of instances, a manifestation in the neonatal period of fibrocystic disease of the pancreas (*see* Bodian, 1952). In a preparation stained by hæmatoxylin and eosin, the intestinal contents, while not homogeneous, appear amorphous, and hardly inspire one to attempt a morphological analysis. When stained by the trichrome method mentioned above, using Feulgen hydrolysis and azure A, periodic-acid-Schiff, and naphthol yellow S, the impression is entirely different. The discrete distribution of protein and mucopolysaccharide staining, the areas of protein being associated with numerous nuclei, and the presence of rounded, more compact areas, suggest the possibility that there is here a morphological problem to be solved, and lead one to doubt the current view that the blockage is to be adequately explained merely by the inspissation of more than usually viscous mucoid material.

Thus, histochemical methods, apart from assisting in diagnosis, may be used to investigate the problems of disease, to demonstrate morphological structure, and may themselves uncover morphological problems which were not apparent before.

*Quantitation of Histochemical Staining*

There is a growing tendency to measure the colours obtained by histochemical staining by use of the microspectrophotometer.

A number of people, notable among whom are Caspersson (1947) and Danielli (1953), have set out in detail the optical requirements for accurate quantitation by this method. A second essential is that the intensity of colour should bear a quantitative relationship to concentration of the chemical substance demonstrated (*see* Allfrey *et al.*, 1952). It is obvious that some investigators have made no attempt to fulfil the requirements under these headings. However, such difficulties may be overcome by ingenuity, patience and attention to detail.

A third and more important type of difficulty in achieving quantitation in histochemistry is

[1] Introduced first as a food dye by Johnson and Staub (1927), and as a histological stain by Haynes (1933), it was adopted by Lillie (1940) for use in place of light green in Masson's trichrome stain.

inherent in the tissue with which we work, and is posed by the non-uniform distribution of chemical substances in biological tissues and cells. This problem was succinctly and graphically dealt with by Gomori (1952) in his book "Microscopic Histochemistry". Suppose we have a given amount of coloured substance continuously and uniformly distributed which allows transmission of 5% of light of the wavelength used—in other words a dark colour. If the same amount of coloured substance is discontinuously distributed so that it covers only half the field, the amount transmitted will be 52·5%, and if aggregated to cover a tenth of the field, 90·5% of the light will be transmitted. The range of error is thus enormous. If the colour is lighter, the error is less, but still substantial. If the transmission with uniform distribution is 50%, the other figures will be 75% and 95%.

I do not wish to detract in the least from the achievement of some workers, such as Caspersson and his school, in applying quantitative methods to histochemistry, although one feels that at times their claims are somewhat optimistic. I do wish, however, to suggest that all claims of quantitation in the field of histochemical staining should be received in a spirit of scepticism and subjected to the closest scrutiny before being accepted. Certainly one should strive to replace, where possible, subjective assessment by objective measurement, but the judgment of a trained observer is still to be preferred to the spurious accuracy of misleading figures. Whether accuracy of quantitation has, in fact, been achieved can perhaps only be judged by the expert with knowledge of the optical system used and the chemical reaction involved; but it is the knowledgeable morphologist who is in the best position to decide whether or not, in any given circumstances, quantitative methods may be validly used.

I have mentioned the extrinsic and intrinsic technical difficulties of quantitation as applied to histochemical staining, leaving aside the wider questions of possible differences in the localization and amount of chemical substances in dead as compared with living tissues, and of artefactual effects produced during treatment of the tissues.

Certainly, accurate quantitation is occasionally possible in histochemistry, and somewhat more commonly a very rough degree of quantitation is possible and may give significant results, but, it is suggested, with almost all problems the only quantitation which has validity and significance is of the order—yellow, very yellow, faintly yellow, or not yellow at all.

# The Problem of Cancer of the Lung in the Industrial Area of Liège during Recent Years

By Professor J. FIRKET

*Directeur, Institut de Pathologie, Liège, Belgium*

(With the assistance of the late Professor Batta, and of Mme Castermans, M. Desoignies, M. Van Lancker, Mlle Thomas)

THE information that we acquired from the study of air pollution in Liège is our reason for giving this paper.

At the end of December 1930 a dense, poisonous fog occurred in the Meuse valley. There were about 9,000 people living in an area, half rural, half industrial, who suddenly collapsed on the third or fourth day of this severe fog—80 of whom died a few hours later. The fog had spread all over the east of Belgium. It was not specially dense in Liège, but was very noxious in the industrial valley for a distance of 10 to 15 kilometres directly upstream from Liège. In that area most of the patients, and especially those who died, showed on the third or fourth day slow, gasping breathing, cardiovascular failure, hypotension and alkalosis (Fig. 1). Death occurred after only a few hours.

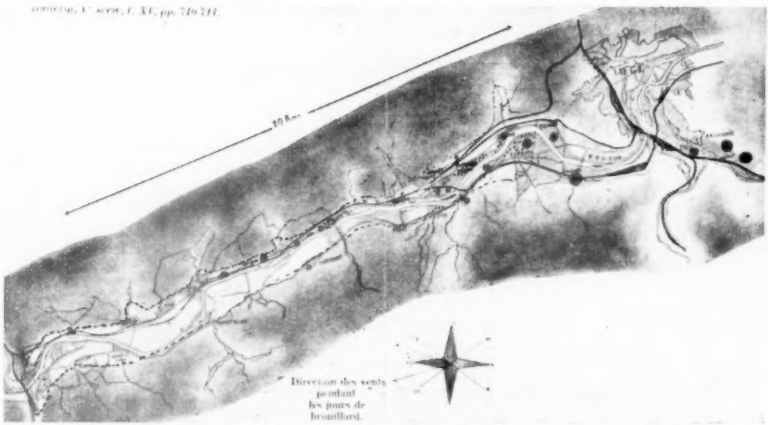

FIG. 1.—Chart of the toxic fogs in the Meuse Valley, upstream from Liège.

*Reproduced from Firket (1931) by kind permission.*

While carrying out our research we found the results of some chemical analyses in the University archives which had been made quite fortuitously during the year 1899. In these the quantity of sulphur on the soil had been measured immediately after snow had fallen and washed the atmosphere while falling. In the same places, thirty years later, our chemists found ten times as much sulphate in equivalent amounts of freshly fallen snow.

During the year 1931 we asked our British colleagues, in particular Dr. J. B. Haldane, how toxic incidents, similar to those we had experienced upstream from Liège, had never been observed in London during dense fogs which lasted longer than ours. Haldane replied that heat emanation from such a large concentration of people living in London, prevented the meteorological ceiling from descending so near to the ground and that therefore the fog polluted by industrial smoke could spread freely and laterally towards the neighbouring hills around the city. In fact, we know that particles of soot, acidified or not by $SO_2$, dissolved in water from the fog, did not fall quickly to a level where human beings could inhale them. The risk of London fogs reaching a threshold of toxicity was not therefore, at that time, so great and severe respiratory complications were less likely to occur. If we use Stokes' formula, we find that, during cold, foggy weather with no wind, a particle of soot 1 $\mu$ in diameter and issuing from a chimney 80 metres high takes six days to reach the ground. Similarly, in the same meteorological conditions, a particle 2 $\mu$ in diameter would take about three days, and a particle measuring 4 $\mu$, one and a half days.

The steady increase of air pollution in industrial communities during the last half-century is well demonstrated by the three following dates: Professor Prost's results of 1899, the experts' analyses in Liège in 1931 and the London experience of 1952.

But how may these dense, smothering fogs be related to the increased incidence of pulmonary cancer observed at the present day?

The meteorological conditions which caused the heavy mortality in 1930 are quite unusual in Liège. They were caused by the following series of events: a considerable cooling of thick dusty air, a fog filled with fumes (especially sulphurous ones), an east wind of only 1 km. per hour and a meteorological ceiling hanging at an average of 75 metres above the ground. The ceiling was thus lower than the tops of the hills bordering the valley, which are mostly about 80 metres high. The wind was blowing *upstream* very nearly in the direction of the valley. It carried along with it all the dust from the town and although fog covered the town no symptoms of poisoning were reported among its inhabitants.

Similar conditions over a period of over four days have been seen only five times from 1901 to 1930. Twice they caused comparable accidents; once they did less harm, by occurring in a branch rather than in the main valley of the Meuse; and on two occasions they happened during a period when industrial activity was much below normal.

Table I shows the substances which were measured more especially, namely those which caused acute symptoms on the third and fourth days of fog.

TABLE I.—MEASUREMENTS ON 20 KM. OF THE VALLEY UPSTREAM FROM LIÈGE AND TOWARDS HUY

| Nature of products | Toxic content after several hours of exposure | Maximum content reached after 1 day | Maximum content reached after 4 days |
|---|---|---|---|
| $CO_2$ | More than 2% by volume | About 0·4% by volume | About 1½% by volume |
| CO | More than ½% | About 0·03% by volume | About 1½% by volume |
| $NO_2$ | 12 to 16 cg. per cubic metre of air | 1 to 2 mg. per cubic metre | 4 to 8 mg. per cubic metre |
| HF | In the region of 4 mg. per cubic metre of air | 0·08 mg. per cubic metre | 0·3 mg. per cubic metre |
| $SO_2$ | 20 to 30 mg. per cubic metre of air | 25 mg. per cubic metre | 100 mg. per cubic metre |
| $H_2SO_4$ | 4 mg. per cubic metre of air | 38 mg. per cubic metre | 152 mg. per cubic metre |
| | | (On supposition of the complete oxidation of $SO_2$.) | |

A similar smog occurred in 1948 in Donora, an industrial valley in Pennsylvania, and, like the Meuse incident of 1930, aroused the interest of the whole world.

We now have to consider whether the same amount of gaseous substances, including not only the polluted air of the valley but also the air of the city, might not, in some other conditions, bring cancer in its train.

We know that the meteorological conditions which provoked such toxic effects upstream from the Meuse were quite unusual as far as the direction of the wind is concerned. Indeed, the prevailing wind is from west-south-west. It is generally not very strong, with an average speed of 5 to 10 km. per hour. In a general way, Liège and its outskirts which include 500,000 inhabitants live in a foggy or a smoky atmosphere, extending over a wider stretch of ground. Hills border the city on the north side and are about as high as those limiting the valley upstream. Those special conditions should be taken into account when we examine the particular geographical factors of the region, even if they do influence conditions for only a very short time.

When we try to explain the increase in frequency of primary cancer of the lung which has been observed these last forty years in Liège, as well as in Western Europe and in America, we cannot find a single determining factor in any given region. Undoubtedly, primary lung cancer has always existed. When I was in my twenties, it was uncommon, just as primary cancer of the liver still is in Europe, though frequent in the tropics. And when it first became obvious, say between 1920 and 1930, we believed the increase in frequency to be only apparent and resulting from better methods of radiological, cytological or clinical detection. It gradually became clear, however, that the increase was real.

For the last fifty-four months we have diagnosed, in the whole Province of Liège, 820 cases of primary pulmonary cancer, of whom 788 were men and 32 women. All these cases were confirmed either by biopsy or through exfoliative cytology or by both. Among the 900,500 citizens in the province a number of pulmonary cancers must have escaped our microscopic investigation. If this disease were spreading throughout Belgium among the population at the same rate, it might be said the total number of patients suffering from pulmonary cancer in the whole country was about 6,000. These figures almost agree with the Dutch cancerologist Korteweg's opinion, when he says that primary lung cancer is

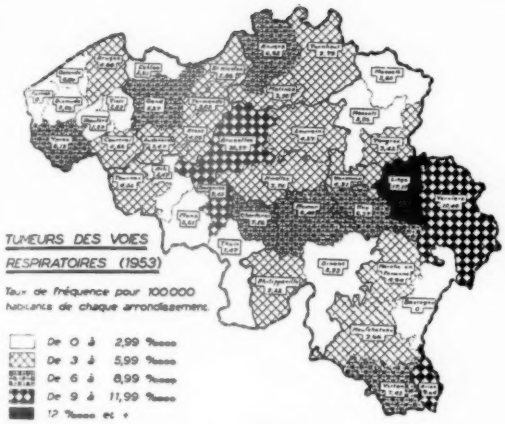

FIG. 2.—Map of Belgium giving the primary lung cancer in the different districts.
*Reproduced from Tuyns (1954) by kind permission.*

fast approaching 40% of the total mortality due to cancer in Western Europe. Those figures should draw the attention of the Belgian medical authorities to the fact that unless 250 or 300 new cases of pulmonary cancer per year are discovered out of every one million of Belgians (a number below the populations of each of the provinces of Antwerp, Brabant, and Flanders and Hainaut) our methods of examination have not been sufficiently thorough (Fig. 2).

In our province of Liège we appear to have the highest incidence in the whole of Belgium. But, until we can be sure of the efficiency of our detection system throughout the country we do not feel justified in concluding that the incidence varies in the different regions. No doubt our province has been somewhat favoured because all pathological and microscopic examinations are centralized in our Department of Pathology. This department is run as a public service and during the last five years has undertaken more exfoliative cytology than any other centre in Belgium.

Why primary cancer of the lung has been increasing is one of the most important problems of pathology which our generation has to face. Some types of lung cancer seem to be particularly responsible for the general increase. Next in frequency were two other types of adenocarcinoma: pulmonary adenomatosis and cancer arising from bronchial glands (Figs. 3, 4, 5).

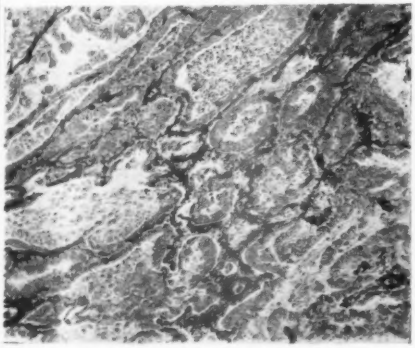

FIG. 3.—Adenomatosis with mucus in the epithelial cells and elastic fibres of the stroma stained.

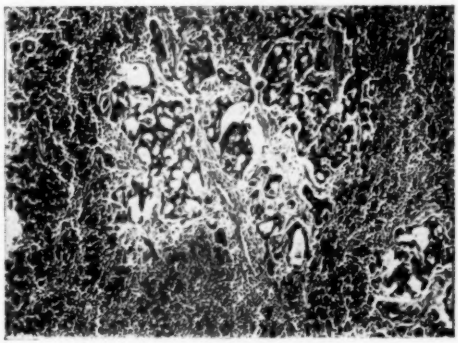

FIG. 4.—Metastasis of the same cancer in a hilar gland.

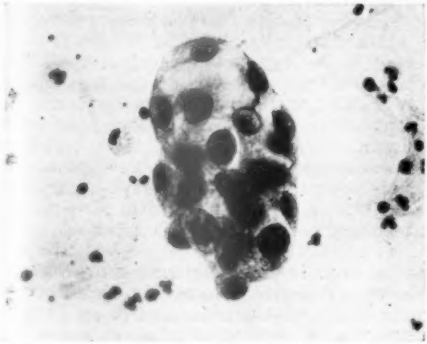

FIG. 5.—Smear by the Papanicolaou method of an adenomatosis.

In 1942, Neubuerger and Geever identified 25 cases definitely similar to these last, and 15 doubtful ones. In 1954 one of my assistants, Dr. Desoignies, reported 4 such cases. The comparatively small number of this type of case, which seems to affect women as well as men and often leads to metastases or to several secondaries, seems to constitute a particular type, "the alveolar tumour". This appears to be as malignant as any other type of pulmonary tumour. Morphologically it has been compared with the "jaakziekte" of sheep which is certainly due to worm infestation (Dungal, 1946). With many others we tend not to classify these last tumours with those we referred to at the beginning. But the question has become all the more important since Campbell and Kreyberg (1956) appear not to agree with this opinion. The fact that tumours of Kreyberg's second group occur in an equal number of men and women seems to point to endocrine origin.

Both by clinical observation of human cancers and by experimental cancerology, certain aspects of the pathogenesis of spontaneous cancers are well established.

Firstly, it seems clear that every cancer requires a previous alteration in the tissues from which it originates. This alteration may be either regenerative, hyperplastic or metaplastic, and precedes the appearance of cancer sometimes by many years. Recent observations of cancers "in situ" help to illustrate this fact. Secondly, any cancer is almost certainly the result of the cumulative or combined action of several factors, intrinsic or extrinsic, of which each particular form of cancer has its own combination. The causes may be the presence of a virus, deficiency of a food, exogenous or endogenous toxin, or the lack or excess of a genetic or endocrine factor. I am convinced that in the present case, carcinogenic hydrocarbons play a part and 3:4 benzpyrene a predominant one. Stocks and Campbell (1955) show figures from England and Wales which indicate that certain quantities of benzpyrene, expected to have been inhaled with air or cigarette smoke play a most important part. This was the basis for further work devoted to pulmonary incidence of various degrees of air pollution, in other countries where conditions are quite different. Thirdly, any spreading cancerization is the result of carcinogenic factors that must exert their action for a very long time. Pulmonary cancers observed in the miners of Schneeberg, which certainly may be ascribed to radioactive dust from nickel, arsenical cobalt, silver, &c., did not appear until at least eighteen years had been spent at work in the dusty galleries. Often they only appeared several years after the men had ceased from this noxious work.

But apart from these general ideas, we are much less well informed as to the part in carcinogenesis played by chronic infectious processes in the bronchi, chronic bronchopneumonia, bronchiectasis, the effects of poison gas, or by psittacosis. We cannot believe that the pandemic influenza towards the end of the First World War bears a particularly heavy responsibility, in spite of the bronchial metaplasia it caused. Moreover, in 1923, Staehelin (1919) in Basel pointed out that his post-mortem department had recorded an increase in the frequency of primary pulmonary cancers which had started in 1912—some five years before the 1917 epidemic of influenza. A similar observation had been made by Mönckeberg in Strasbourg before 1914.

The direct experimental approach to the problem in man seems very promising when we consider that several chemicals may lead to primary tumours in lower animals following their inhalation and especially in view of Blacklock's (1957) evidence that the intrapulmonary inoculation of hydrocarbons such as 3:4 benzpyrene or methylcholanthrene can induce both sarcoma and carcinoma of the lung in rats. Yet, it is certain that though several tumours have been produced, none has resulted from a direct action of a carcinogenic hydrocarbon on the respiratory epithelium. They have certainly been produced in sarcomas in the body of the tissue but not in the recovering epithelium. That is why the experimental techniques used by Andervont (1939) by means of threads set with crystals of dibenzanthracene were able to transform recovering epithelium into one type of cell or another. Thus one is struck by the numerous factors which lead to a similar result. Over 200 organic substances, or even plain metals, proved to be carcinogenic towards one animal species or another, by means of such a technique.

On the other hand, virus, food deficiencies, hormonal alterations, and radio-activity can have a similar effect. And we must only conclude that carcinogenic agents are so many and so diverse that it is virtually impossible for any tissue to escape all exposure to irritating factors which, as the years go by, become more and more varied, and are made in ever larger quantities.

On studying the literature on occupational and environmental factors, we find that uranium and its substitutes, chromates, nickel, beryllium, and some carcinogenic hydrocarbons are chiefly incriminated. These are all substances of frequent use in industry. We also find a good deal of pulmonary cancer among men working with asbestos in mines where pneumoconiosis occurs. Yet we must acknowledge that the causal relation is seldom fully established.

Hammond and Machle (1956) have accepted, as we all do, a connexion between cigarette smoking and lung cancer, yet we must admit that the first approach to this problem was only conjectural. Hammond and Horn (1958) made an enquiry in 1954 bearing on 187,783 men, of whom 4,854 died within approximately twenty months from the time they were questioned. According to the death certificates, 844 were due to cancer, of which 167 were attributed to primary cancer of the lung. Then, Doll and Hill (1950) made a preliminary report on a similar study of 24,389 British physicians, aged 35 and over, and followed for twenty-nine months (Table II, from Mayer and Maier, 1956).

TABLE II.—SUMMARY OF FINDINGS REPORTED BY 14 RETROSPECTIVE CLINICAL STUDIES ON THE ASSOCIATION OF SMOKING AND LUNG CANCER

| | | No. of cases | | % who were non-smokers among those | | % who were heavy smokers among those | | Relative risk of lung cancer | |
|---|---|---|---|---|---|---|---|---|---|

| U.S. | 1953 | 63 | 133 | 4·1 | 20·6 | 67·6 | 29·3 | 6·1 | 11·6 |
| U.S. | 1953 | 477 | 615 | 3·8 | 13·2 | 46·8 | 30·7 | 3·8 | 5·3 |
| Fin. | 1953 | 728 | 300 | 0·6 | 18 | 65·8 | 20 | 36·4 | 79 |
| U.S. | 1954 | 518 | 518 | 3·7 | 10·8 | 75·6 | 44·2 | 3·2 | 5 |
| U.S. | 1954 | 490 | 2365 | 8 | 26·9 | 52·7 | 22·7 | 4·2 | 7·8 |
| U.S. | 1954 | 265 | 287 | 1·9 | 9·7 | 73 | 57 | 5·5 | 6·5 |

We see that an association between cigarette smoking and cancer has been difficult to bring out clearly, even though no one to-day would deny its existence and importance. We are of the opinion that cigarette smoking is one of the causal factors in the development of lung cancer, but that its relationship may not be a simple one.

### GENERAL ATMOSPHERIC POLLUTION

Only a small proportion of our population is employed in factories or industrial firms where there is a considerable risk of contracting lung cancer. But the whole population inhales the air which is polluted in various degree by many organic substances. Most of the pollution is from soot, smoke from coal and fuel oil and fumes from motor cars or tarred roads. In general, whenever an organic material is heated, carcinogenic elements are liable to be introduced into the atmosphere, either by distillation, or following cracking or burning. In combustion, hydrocarbons yield a great variety of substances which tend to concentrate on cooling and Campbell and Kreyberg (1956) have used the benzpyrene content as an indicator of hydrocarbon pollution.

The same point could, of course, be made about radio-active substances. These were comparatively rare some fifteen years ago, before the present vast production of radio-isotopes for military and scientific purposes got into its stride. Factories dealing with thousands of tons of uranium must, surely, be sources of activity, whatever the proportion of air-scatter from them may be. Nevertheless, systematic analyses show that the cancer rate of the general population is comparatively little increased from this particular source.

We thought it might be interesting to show a record of five years in the life-history of 500 pulmonary cancer cases living in a city in which the distribution of airborne dust is fairly well known. In Fig. 6 we have plotted the place of residence of known cancer patients on the map of the Liège area, and the valley joining it from the south-east. Generally it would appear (Fig. 6) that the houses of cancer patients are largely concentrated in the centre of the city, stopped by the hill bordering the city in the north, extend eastward, north-east, and some south-east. But if we look in detail at that distribution of dwellings, we see some interesting facts. Many workers are busy in the huge metallurgic establishments just upstream of the City (Cockerill and Ongare). These workers live in dwellings which were built for them about ten to fifteen years ago. Because of the prevailing wind, the area which they all occupy is one of the least polluted by chemical dust. Yet the number of pulmonary cancers is fairly large. In contrast, in the centre of the area which is surrounded by a horseshoe of the Meuse, immediately north-east of the first

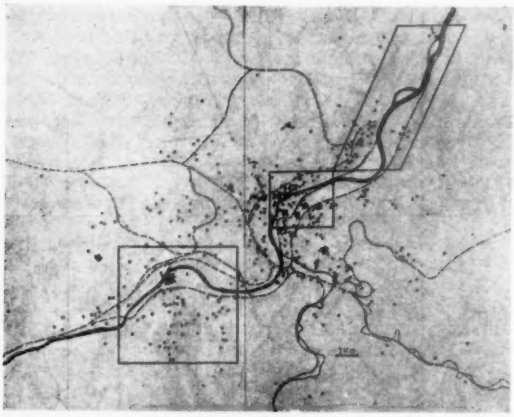

FIG. 6.—Map of the City of Liège and outskirts with in black points all the residence of the patients affected with lung cancer during the last five years (1952–1957).

area, there are few cancer patients, even though this is a sort of tableland on which dust is rather abundant. But there is no industry on the plateau and it has been a pleasant residential area for about forty-five years with many trees and occupied by the well-to-do middle class. The high dust pollution of this area was, of course, not known at the time it was built.

We have been struck by the large number of persons with cancer living in the centre of the city and especially in streets beside railways or canals carrying coal-burning boats. Our attention is drawn to these by their names, "Rue de la Gare, Rue de la Station, Rue du Chemin de fer, Rue du Vincinal". Railway engines are an obvious source of air pollution and steamboats also clearly pollute the air around docks. These sources have been emphasized recently in Canada. During 1955 the incidence of lung cancer was found to be five times higher among engine drivers than among the whole population in the same neighbourhood. Engine drivers of course inhale carcinogenic hydrocarbons either from the sooty exhaust of diesel engines or the smoke of coal-burning locomotives.

In Belgium, too, we can see a striking correspondence between smoke and lung cancer. In the vicinity of factories in Herstal, including the famous Belgian Fabrique Nationale, one can find many men out of work because of cancer. But as the valley runs north the incidence suddenly drops and, at the same time, the smoke disappears and the sky assumes the lovely milky hue it shows in Holland and which has been rendered famous by the Dutch painters of the eighteenth century. Towards the east the smoke continues and with it the cancer.

From our five years of research we must conclude that lung cancer has a complex ætiology. Of several causes cigarette smoking is a very important, but not always an essential, one. Indeed, it seems to us that polluted air, and particularly the hydrocarbons contained in soot, remains the most important cause.

## DISCUSSION ON SEDATION AND STIMULATION OF MAN

**Dr. William Sargant** (London):

The value of a physical approach to the healing of the spirit of man, as well as to the healing of his body, has been demonstrated beyond any shadow of doubt in recent years. In the last quarter of a century we have, in fact, watched a whole range of psychiatric syndromes and their treatments being taken over, lock, stock and barrel, from psychiatry by general medicine, and many syndromes have certainly proved themselves to be much more efficiently treated by the mechanistic methods of modern medicine, and along mainly physiological lines. The conquest of G.P.I. with penicillin, the abolition of pellagrous madness with nicotinic acid, all the mental states responding to recently synthesized vitamins and endocrines, and now the success attending the use of insulin, E.C.T., leucotomy and the like, are all examples of this. It should not, therefore, be at all surprising to find that very few patients to-day ever reach psychiatrists without physicians or surgeons first also having attempted to influence the mind with some form or other of sedative or stimulant drug, and that we are now using so many more and varied types of drugs for such purposes.

There are many people, however, who feel that the chemical treatment of the mind is something morally discreditable, and certainly not to be encouraged—except perhaps for the purpose of getting other people to pay as much in taxes as possible. And we certainly cannot ignore all the heavy overtones of ethics and morality which constantly burden discussions of this nature. I am sure that among my readers will be found some who feel that the provision of courage, will-power, and freedom from anxiety by means of bottles of medicine or pills is very wrong indeed. This is a problem which must be faced straightaway. World Health Organizations and other detached and often well-meaning bodies, and individuals, may continue to deplore the increasing use of various sedative drugs and tranquillizers, and certain persons, obsessed with their own great power of self-control, or proud of their remarkable strength of will, may continue to write to medical and other journals, deploring the use of almost any form of sedative or stimulant by man. But the doctor's first and foremost duty is to try to treat his patient in as efficient and practical a manner as possible, and to help to the best of his ability those coming to him for relief of often intolerable and incapacitating nervous symptoms, whether they be psychologically or physiologically determined. It is complete and utter nonsense to say we are a nation becoming medically dependent on chemical aids to the attainment of spiritual grace. But we are becoming more sensible medically, I think, about the unnecessary, avoidable and often physically exhausting nature of much human mental suffering, which can be so much worse than physical suffering.

My only three months' experience in general practice, obtained in between two of my training posts in psychiatry, showed me, in fact, how many people may be helped by sensible and simple remedies, such as a bottle of bromide or even a double whisky, as opposed to the use of skilled specialized psychiatric talk and religious or moral exhortation. Those who insist on the supreme value and the absolute need for specialized psychotherapeutic treatments of the neuroses are often those who are almost blind to what can be achieved more simply in so many instances by the skilled use of stimulant and sedative drugs. Millions of pounds in pensions were, for instance, saved in World War II simply because it was at last realized that immediate and heavy "front line" sedation was generally more effective in the prevention of chronic neuroses, and of so-called "malingering" reactions, than all the threats of shooting for cowardice and the verbal exhortations and moral punishments used instead as treatments from time immemorial. Both physical and psychotherapeutic methods of treatment are, of course, best combined in many patients. It is important that we always try to use only those drugs which are the least harmful and the best tolerated by the individual, and which do not cause too severe psychological and physiological symptoms when they have to be withdrawn or curtailed.

It is impossible to mention here anything more than a fraction of the numerous sedatives and stimulants now available for treating the mind of man. I shall try to keep mainly to some important general principles of their use. In considering the increasing range of chemical aids to sedation and stimulation, we can easily find ourselves becoming very bewildered and confused. For chemical manufacturers are now producing and advertising extensively many new drugs, and many new combinations of new and old drugs; and so

many drugs are given a succession of new trade names, and so many impressive trade names are being attached to sometimes old and quite worthless remedies that all this may lead to a state of medical and lay drug intoxication and confusion, which will almost certainly result in doctors giving up, wrongly, some of the still valuable older drugs, and passing over other valuable newer drugs. For example, I believe that the initial advertising and claims for chlorpromazine, and the pressing of its use on the general practitioner, long before most psychiatrists in this country had any chance to test it out in specialized centres, nearly resulted in its being discredited and given up in many quarters. It has proved eventually to be a valuable, even if limited, new sedative drug. But it is only now, some four years after its introduction, that many of us are starting to learn how to use this drug properly, in part because of all the early claims and counter-claims that so confused the minds of the ordinary doctors and those of many psychiatrists as well.

Another source of possible confusion is the present vogue for the testing of these new drugs by double-blind sampling methods. Such methods can sometimes be a source of as much misinformation as they are of useful information. We may learn, for instance, from such methods that over the whole range of varied neuroses chlorpromazine or Equanil is not much more effective than small doses of Sodium Amytal, and also, incidentally, is very much more expensive to prescribe. But what it may be really important for us to find out is whether or not Amytal can help a particular small group of neuroses better than chlorpromazine can, or whether chlorpromazine helps other small groups which are untouched by Equanil. There is now a tendency to lump too many psychiatric states together in the testing of these new tranquillizers, and this is as bad as was lumping together all fevers in the old days to find out whether or not, for instance, quinine was of any use as a febrifuge. Double-blind sampling tests would probably have led to the finding that quinine was no good at all for fevers in general, and one might then have missed completely the fact that it was indeed of the greatest value in the treatment of malaria.

A point which needs to be emphasized is the importance of the correct dosage. Pavlov showed in his dogs that what he termed the "strong excitatory" dog might need no less than eight times the dose of a sedative drug needed by the "weak inhibitory" dog. He stressed also that if drugs were to have their best therapeutic effects in relieving the experimental neuroses he induced in his animals, correct dosage was of the utmost importance; to give a "strong excitatory" dog the "weak inhibitory" dose of any drug was absolutely useless, and to give the "weak inhibitory" dog the dose needed by a "strong excitatory" animal was to make its neurotic condition much worse rather than any better. Experience in psychiatry has confirmed the importance of Pavlov's observations, which are equally applicable to man. There are just as many various types and constitutions in human beings as there are in dogs, and these constitutional types are very differently tolerant of the same doses of a drug. Some of our schizophrenic patients, for instance, are walking about and greatly benefiting from being treated with over 600 mg. of chlorpromazine a day, and are being little upset by such large doses. Other patients with hysterical illnesses may fall about and be worsened by taking only 25 mg. of the same drug three times a day. We all know the strong excitatory businessman who is only mildly sedated with half a bottle of whisky, and who merely laughs at a capsule of Sodium Amytal as a sedative; his weaker inhibitory colleague, on the other hand, may be made quite drunk by a capsule of Sodium Amytal, and would have a hangover for many hours from a dose of whisky taken merely as a mild stimulant by his stronger and more forceful colleague. It is these varied medical and constitutional considerations, which are always with us, that may lead us astray in our endeavours to find the proper uses and dosages of new drugs.

Subject to many provisos, one can say that the last quarter of a century has shown us some valuable apparent progress in trying to find more satisfactory chemical sedatives and stimulants for man. Whether many of the newer ones are really very much better than the old ones cannot, however, yet be said with absolute certainty. Fashion and authority in drug prescribing may certainly change in the most startling way. I was trained at St. Mary's and in the school of the late Sir William Willcox. At that time the giving of any barbiturates at all was considered a major therapeutic crime. This did, however, give one the opportunity of exploring the value of several other drugs and sedatives. One learned, for instance, the value of very large doses of aspirin, given both as a sedative and pain-reliever, and how effective this could be in some patients. Though I played a part in bringing to light the amount of bromide intoxication occurring at a time around 1936, when bromide was about the fourth most widely prescribed drug under the old panel system, and this helped towards its present disuse and discredit, nevertheless there are still certain patients who seem to be helped by bromide perhaps more effectively than by many of the newer or older tranquillizing drugs. Obsessive tension states seen in the human, and possibly equivalent to some of Pavlov's stronger excitatory states in dogs, are often very poorly helped by barbiturates. If such people take barbiturates in reasonable doses they may obtain very little benefit; small amounts of

barbiturates may even make these patients more excited and tense rather than relieve any of their anxiety. Addiction to much larger doses of barbiturates may, alternatively, develop. Other explosive personality types sometimes have equally unfortunate reactions when small doses of barbiturates are prescribed. I believe there is still a field for the use of bromides in some tension states. It is certainly difficult to believe that the enormous amounts of bromide used for so many years, both in psychiatry and in general medicine, were of no value at all, although this drug has now become almost totally discredited.

Turning to the barbiturates, they are perhaps the most effective routine sedative we have at our disposal for the majority of our neurotic patients. Especially in the neuroses they are undoubtedly as efficacious in the general run of patients as are the newer tranquillizers, such as Largactil and Equanil; the trouble is they are often too efficacious. The fact is they not only relieve anxiety but also create pleasant states of euphoria, and it is this euphoria which increases the tendency to undesirable addiction. In rebellion against some of the absurdities of my St. Mary's teaching on sedatives, I was one of the first persons to advocate a much wider general use of the short-acting barbiturates as a routine sedative. In the first edition of my book with Eliot Slater "An Introduction to Physical Methods of Treatment in Psychiatry", in 1944, I made the statement that these barbiturates, in moderate doses, did not cause addiction in the true sense of the word, nor severe symptoms on withdrawal. But I think this statement has now to be modified. For I, with others, have come to realize that patients with chronic tension states may continue to remain tense and anxious for many years, because they are, in fact, suffering more from a self-induced or doctor-induced chronic barbiturate tension state than from a persisting anxiety neurosis *per se*. I am now seeing patients who have had one, two, or even three leucotomies performed for a chronic persisting tension, and who have then turned out to be, probably, cases of chronic barbiturate addiction. If they can be weaned from their barbiturates, their tension may still resolve, even after the failure of their leucotomies to help them. One sees fewer of these patients addicted to the longer-acting barbiturates, such as phenobarbitone and sol. barbitone. These two drugs are, of course, not so efficacious in regard to the temporary relief of tension as the short-acting barbiturates, and they also create much less euphoria which is such an addicting quality in any drug. The new tranquillizers, such as Largactil and Equanil, also do not create such undesirable states of euphoria in the neuroses. But they may also be less effective in bringing relief of anxiety in many neuroses, despite Largactil proving to be so valuable in the treatment of some acute and chronic psychotic patients. Equanil can produce some very favourable results indeed in selected neuroses, but it is still difficult to find out exactly which groups of neuroses are most helped. I have gained the impression, however, that it is the patient showing mixed obsessive and hysterical symptoms who is often helped by Equanil in the clinical dosage usually prescribed. Equanil also seems to be of considerable help in alcoholic withdrawal states. Severe obsessional states are not generally helped by either of these two new drugs. The great danger of another new drug—Serpasil—in the neuroses is that it can produce such severe states of near-psychotic depression. Undoubtedly many suicides have been caused because general practitioners were persuaded into using it in patients with neuroses and early psychoses, and normals with hypertension, before these and other complications of the drug had been discovered by trials in expert hands.

I feel myself quite unable to discuss many of the new tranquillizers that have recently been introduced. It may take one several years to learn how to use a new drug properly and skilfully, and I think the only hope for all of us at the present time is to try to stick to a limited range of drugs, both new and old, and to concentrate on trying to master the proper use of a few drugs, rather than to play around ineffectively with too many. For instance, one should learn how to handle a good short-acting barbiturate, a medium, and a long-acting one; these together with one or two of the new tranquillizers, such as Largactil and Equanil, will prove to be a fairly satisfactory range of sedatives to use in clinical practice at the present time for neurotic and normal patients.

Turning for a moment to the sedation of psychotic patients, many of our problems arise also from ignorance as to the correct dosages to be administered to our varied groups of patients, and we know as yet little about the length of time drugs need to be given to obtain the best results. We have seen this recently in the treatment of schizophrenia by Largactil. Originally much poorer results were being obtained in England with this drug because it was not always realized that very much larger doses were often needed in the treatment of schizophrenia than in normal persons or neurotics. Maintenance doses of from 400 to 800 mg. a day may be needed to help some patients, who may get about or go back to work on such doses. But the use of similar amounts in severe depressive illnesses might well drive a patient to suicide by greatly increasing the depressive features present. And one must be very guarded indeed in ever using Serpasil in patients with a history of previous psychotic or neurotic depression, while being prepared to use it, if necessary, in very large doses in the sedation of schizophrenia. What we do not know yet is how long such drugs have to be kept on in

patients in whom these drugs appear to be helping to hold at bay a schizophrenic illness. Some of us have had patients on Largactil for months or years already, with an ever-present danger of relapse when the dosage is stopped or lowered. But such findings do suggest that we may be on the verge of new and exciting developments in the more practical biochemical treatment and handling of some schizophrenic and other psychotic patients.

It is unfortunate that much less effective stimulants than sedatives have so far been developed. Again we are also seeing more addiction than we used to with amphetamine drugs, but it is still very much less than with the barbiturates. This is often because the taking of too much Benzedrine creates sleeplessness, and those searching for euphoria and temporary oblivion do not appreciate too many long nights without sleep. However, one must recognize those states of paranoid confusion which result from the taking of Benzedrine in too large a dosage and for too long a time. This can precipitate people suddenly into mental hospitals, often quite wrongly diagnosed as schizophrenics; the symptoms, however, clear up rapidly when the drug is withdrawn. We have also learned how ineffective amphetamine and allied drugs are in the treatment of any but mild cases of depression. The only advantage of some of the recent substitutes, such as Preludin and Meratran, has been in the absence of some of the side-effects which Benzedrine often produces. But Meratran itself in very small doses can occasionally cause severe and most unpleasant temporary psychotic complications.

I have given only a very rough outline of some of the main principles which seem to be so important in the use of sedatives and stimulants in man. May I end with a plea that, in using the ever-increasing range of new drugs, we do not rush too madly from one set of new drugs to another. Let us look around and see where the main gaps are in our present therapeutic armamentarium, and try to encourage the development of drugs which will help to fill these treatment gaps first of all. Some advances have been made, I think, in the treatment of anxiety, but very much better drugs are still needed in the treatment of obsessional states and depressive reactions; and we are also looking out for new and better sedative drugs in the treatment of the schizophrenias. We must not be too ready to abandon the old for the new, until we have learned how to use the new skilfully and economically, and in centres properly equipped to test them out. This will help to avoid some of the real disasters we have seen in recent years in the too hasty foisting of new tranquillizers on to the general practitioner and public alike.

Finally, let us remember that well-known prayer for "all sorts and conditions of men"; and let us not forget that all of these people will need very different types and strengths of sedation and stimulation, if they are to obtain the help they so often ask of us to-day. Let us never make the mistake of thinking that there will be any real short-cuts or cheap universal remedies in the skilled chemical treatment of the spirit of man.

**Professor E. J. Wayne** (Glasgow):

I have assumed that it is my special task to deal with the pharmacological background of this subject and I intend in addition to examine critically the results reported by clinicians on the use of drugs which sedate and stimulate man.

Early in his history man recognized the effect of two naturally occurring drugs, alcohol and caffeine, which he still consumes in vast quantities. Any satisfactory depressant or stimulant drug must be more effective or have fewer side-effects than these and should preferably be at least as cheap. Since states of over-activity and nervous tension are more common than states of depression I intend to deal first and more fully with the sedative group of drugs. Alcohol's earliest competitor was phenobarbitone and this drug is still widely used. It is probable that most hypnotics act as sedatives when given in small doses and the short acting hypnotics such as amylobarbitone are very effective daytime sedatives when given in this way. With the introduction of the antihistamines, the opinion that sedation could be produced only by substances which in larger doses caused first sleep and then anæsthesia was found to be incorrect. In both animals and man these drugs in small doses have a sedative effect and in larger doses produce drowsiness while even in lethal doses anæsthesia is not produced.

A feature of recent pharmacological work has been the search for drugs which will relieve anxiety and tension without impairing clarity of thought or initiative. The idea of a tranquillizing drug came many years ago to Aldous Huxley when he described in "Brave New World" his hypothetical substance "soma". Observations on animals lend support to the view that there probably are drugs of this kind which tranquillize without causing sleep. Thus a substance such as reserpine may convert wild jungle-bred monkeys into calm and unafraid animals. Jacobsen and Sonne (1955) have described methods of producing experimental neuroses in animals and have shown that benactyzine may diminish conflict-induced symptoms. Thus, for example, a rat which expects the sound of a buzzer to precede a mild electric shock stiffens into a characteristic position whenever it hears this noise. Re-

treatment with a tranquillizer may render the animal indifferent to the stimulus. Electrical stimulation of the hypothalamic area may be used to produce outbursts of sham rage which can be prevented by drugs such as reserpine and chlorpromazine.

The mechanisms by which these drugs produce their effect is obscure, mainly because we still know comparatively little about the chemical transmitters in the central nervous system. There is some evidence, however, that acetylcholine, noradrenaline and 5-hydroxytryptamine (5 HT) may all play a part in central transmission. It is tempting to link the action of reserpine with the fall in hypothalamic noradrenaline content which can be shown to occur when reserpine is injected. It has also been suggested that reserpine may act through the release of 5 HT since this substance on injection into the cerebral ventricles of cats causes, like reserpine, loss of energy and signs of lethargy. The hypothesis is supported by the fact that 5 HT antagonizes lysergic acid diethylamide (LSD) a potent hallucinogen resembling mescaline in its pharmacological effects, both reproducing some of the mental phenomena associated with schizophrenia. The more recently introduced compound azacyclonal (Frenquel) has been shown to correct the electroencephalographic changes induced in animals by LSD and mescaline and to abolish the experimental psychosis produced in humans by these substances. Several of the tranquillizing drugs, e.g. benactyzine, are powerful anticholinergic agents but other anticholinergic substances such as atropine do not tranquillize, possibly because they are unable to penetrate to receptor sites. It has been suggested that benactyzine blocks pathways between the cortex and lower levels of the central nervous system. These pharmacological aspects have been well reviewed by Lewis (1958).

It is thus clear that our knowledge of both the nature of the chemical transmitters in the central nervous system and also of the effect of drugs upon them is too small to enable clear-cut statements to be made. Nevertheless, the speculations these ideas have produced have already been fruitful in producing many new sedatives.

It is against this background that these newer tranquillizing drugs must be assessed. They may be divided into two main groups roughly corresponding to their main use in psychiatric states. The first group which includes chlorpromazine, promazine, reserpine and azacyclonal are of value in some psychoses and especially in schizophrenia, mania, senility and children's behaviour disorders. They have also been used with some success in the management of drug addiction, in the control of nausea, vomiting and hiccup and to potentiate analgesics especially in the terminal stages of malignant disease. The balance of evidence is strongly in favour of their therapeutic activity and the only objection to their use is the incidence of side-effects. This is greatest with chlorpromazine and reserpine. Promazine seems to have fewer untoward actions but has been in use for a much shorter time. Azacyclonal is a relatively safe drug but is mainly of value in the treatment of hallucinated patients and by no means all of these respond to it.

The second group of sedative drugs consists of those which are used predominantly in the treatment of the neuroses. Methylpentynol when first introduced was thought to produce sedation without clouding of consciousness but has proved a disappointing drug. Its action is very like that of alcohol and it may give rise to a variety of side-effects. Goulding *et al.* (1957) could not distinguish it from inert mixtures when given in a double-blind trial to children before dental operations. From a pharmacological point of view the actions of the other members of the group are dissimilar but in man they all act as depressants. The most widely used is probably meprobamate which is alleged to relieve fear and anxiety. In the U.S.A. 50 tons a month are consumed, equivalent to 150 million tablets a year costing £2,200,000. Meprobamate has an action similar to that of mephenesin in that it blocks multineuronal reflexes and so relaxes muscular tone. The use of both these drugs as sedatives is based on the view that if in anxiety the degree of muscular tension is relieved there will be a corresponding reduction in psychological tension. There is no evidence for this view and I believe it to be fallacious. In the case of mephenesin a carefully controlled clinical trial by Wolf and Pinsky (1954) showed that it was no more effective than inert tablets in relieving either the subjective or objective manifestations of anxiety and tension. In so far as meprobamate produces its effects through its action as a muscle relaxant it is no more likely than mephenesin to be effective in anxiety states. Its sedative properties are due to a direct action on the cortex not unlike that of the barbiturates. At least three properly controlled clinical trials have been carried out by West and da Fonseca (1956), by Raymond *et al.* (1957) and by Lasagna (1956). The most probable conclusion to be drawn from this and other evidence is that meprobamate is a moderately active sedative of no greater clinical value than amylobarbitone or phenobarbitone. It has the merit of being relatively useless as an agent for committing suicide but its side-effects are many and include hypotension, an itching erythematous rash and, more seriously, purpura. Benactyzine is undoubtedly an active drug when tested on animals and produces symptoms in normal human subjects as well as altering the electroencephalogram. It is therefore somewhat surprising that the balance of clinical evidence is so unfavourable. It ranked no better than inert tablets in several well-controlled clinical trials, those,

for example, reported by Seager and Leitch (1956), Raymond *et al.* (1957), Forbes and Earle (1957) and Coadby and Jewesbury (1956). Raymond and Lucas (1956) and Hargreaves *et al.* (1957), on the other hand, found a greater proportion of patients improved on benactyzine therapy than when control tablets were being given.

The design of some of these trials has been criticized but it is clear that benactyzine is at best a feeble sedative. Minor side-effects such as dizziness are frequent but serious ones are rare. The evidence for the value of two other aspirants to this group of tranquillizers, Covatin and hydroxyzine (Atarax) is not impressive. Taking all the reports together it can be said that when allowance is made for the 35% of any population which responds favourably to any form of therapy including inert tablets (Beecher, 1955) there is little evidence that this group of tranquillizers includes many very active drugs. When they are active they do not appear to be greatly preferable to those barbiturates which are conventionally used in the neuroses. Part of their effect in ordinary practice may be due to a transference from doctor to patient of enthusiasm created by the singularly unrestrained advertising adopted by the manufacturers of some of these remedies.

The place of stimulants in the treatment of psychiatric symptoms is much smaller. We already possess three effective compounds: amphetamine, dexamphetamine and methylamphetamine. There is probably little to choose between them and there is no satisfactory basis for the custom of using dexamphetamine in the treatment of obesity and reserving amphetamine for use in depressive states. There are four newcomers to this field: Mephine is another sympathomimetic amine which is said without much evidence to be less liable to produce anorexia than the amphetamines. Preludin is recommended by its manufacturers for the treatment of obesity and is said not to produce excessive mental stimulation. In fact, however, it is a powerful mental stimulant similar in its effects to amphetamine (Randell, 1957) and it has already been shown to give rise to addiction (Bethell, 1957). On the other hand pipradrol (Meratran) is claimed to be a cerebral stimulant which does not interfere with appetite or nocturnal sleep. Nevertheless Begg and Reid (1956) found some interference with sleep although not with appetite. Gelvin *et al.* (1955) on the other hand were able to demonstrate loss of weight in patients receiving pipradrol when compared with a similar group receiving inert tablets. Houston (1956) found pipradrol no more effective than inert tablets in the treatment of a group of chronic retarded schizophrenics. Methyl phenidate (Ritalin) is chemically and pharmacologically similar to pipradrol. On the whole it seems probable that these newer compounds have comparatively little advantage over the older and better tried remedies but pipradrol may prove to have fewer side-effects than the amphetamines.

Mixtures of sedative and stimulant drugs are widely used especially in general practice and no fewer than seven of these are commercially available. Their use is not wholly illogical since they do not completely cancel one another's effect. Many of us drink strong black coffee after a dinner during which we have enjoyed wine, and it would be idle to pretend that the end-result is the same as if we had taken neither. The objection to these mixtures is the general one that it is rarely possible to mix antagonistic drugs in proportions which will suit every case. In addition they are especially liable to cause addiction. They are better avoided.

It cannot be said that the perfect drug for use in abnormal mental states has yet been discovered and, apart from promazine and reserpine, it is still doubtful if the newcomers to this field have any substantial advantage over well-tested drugs such as the barbiturates and amphetamine. It would be a mistake, however, to be too pessimistic and the time may well be at hand when we are able to tone down the patient's anxiety or tension without impairing his initiative or mental lucidity. Alternatively we may be able to rouse him from his torpor and depression without at the same time producing anorexia and insomnia.

[*January* 22, 1958]

## DISCUSSION ON ENDOCRINE CHANGES IN LIVER DISEASE

**Dr. Sheila Sherlock** (London):

THE liver cells play an important part in the metabolism of almost all the hormones by changing the structure, by conjugation (often as a glucuronide) and so rendering them biologically inactive, and by excretion into the bile. In addition, most of the steroid hormones undergo an entero-hepatic circulation in similar fashion to the bile acids. The changes I shall describe are associated with damage to liver cells and are almost exclusively found in chronic disease (Laennec's cirrhosis). Acute hepatitis is too short an illness for such changes to appear and in biliary obstruction the liver cells function well until terminally.

In cirrhosis vascular spiders are found in the vascular territory of the superior vena cava and very rarely below a line joining the nipples. "White spots" are often associated with spiders (Martini and Staubesand, 1953). They appear on cooling the skin and on the arms and buttocks. Examination with a lens shows that at the centre of each is the beginnings of a spider. Erythema of palms and soles is an exaggeration of the ordinary speckled mottling. These three skin changes have been attributed to hyperœstrogenism for there is evidence that the liver conjugates and inactivates œstrogens, for instance from *in vitro* studies in human liver (Tagnon *et al.*, 1952). Patients with cirrhosis have impaired œstrogen tolerance (Glass *et al.*, 1944). Bio-assay and chemical methods have sometimes shown an increased urinary output of œstrogens in liver disease which does not always correlate with the presence of vascular spiders (Cameron, 1957). Vascular spiders are also found in pregnancy (Bean, 1953). Oestrogens have a dilator effect on the spiral arteries of the endometrium and this might be considered analogous to the development of spiders. They have been induced by œstrogen administration (Bean, 1945) but men receiving œstrogen treatment for prostatic carcinoma do not develop them. Against a hormonal cause are the distribution, and random disappearance of one and simultaneous appearance of another. They have been related by others to increased peripheral blood flow, but we could not relate them to the increased cardiac output often found in cirrhosis (Murray *et al.*, 1958). We must conclude that these skin changes cannot be definitely related to œstrogen excess. Other changes in liver disease have also been attributed to hyperœstrogenism, with consequent secondary pituitary depression. They are specially notable in men, perhaps because women developing clinically evident cirrhosis are often post-menopausal. The changes include testicular atrophy with loss of libido, impotence, sterility, prostatic atrophy and disappearance of secondary sexual hair. Low urinary 17-ketosteroid excretion in liver disease was first described by Fraser *et al.* (1941). This might be related to the secondary depression of the testis but decreased metabolism of testosterone has also been postulated (West *et al.*, 1951) but not confirmed (Williams *et al.*, 1951).

Gynæcomastia is a feature particularly of cirrhosis in alcoholics. It may be due to œstrogenization or œstrogen-androgen imbalance but can also be related to malnutrition. It is particularly conspicuous in alcoholics who are malnourished and less obvious in the post-hepatitic type of cirrhosis seen in this country. An analogy can be drawn to undernourished prisoners of war who developed gynæcomastia when they were re-fed and gaining weight (Klatskin *et al.*, 1947).

The liver plays a central role in the metabolism of adrenocortical steroids. Subjects given intravenous $C^{14}$-labelled hydrocortisone show a lower level in the hepatic vein than in an artery, suggesting that the liver is removing the hormone from the peripheral blood (Plager *et al.*, 1954).

Hepatic disease is often stated to cause dwarfing (Day, 1953; Gregory, 1954) secondary to malnutrition, but I have seen only one girl in whom chronic liver disease might be said to have caused dwarfing and this patient came of short parents. I have plotted the stature of girls with cirrhosis against their age. Until about 10 years the height is near the normal mean; from 11 to 14 years in the majority it exceeds that of 90% of the population in that age group according to Tanner's tables (Tanner, 1958). This may represent an augmented "adolescent growth spurt" (Tanner, 1955). Allowing for ascites and œdema the tall girls

were usually also over-weight. Bone age, based on only a limited number of hand and elbow X-rays, seems within the normal range. Sexual maturation is also normal, although these girls as a group have amenorrhœa or irregular, scanty menses. Urinary 17-ketosteroid excretions are low. Even in normal children, the "adolescent growth spurt" is unexplained and in children with cirrhosis the mechanism is also speculative. It has been attributed to increased androgen production; failure of the liver to inactivate this and/or growth hormone remains possible.

My failure to demonstrate a similar growth curve for boys with cirrhosis emphasizes the interesting sex difference in frequency (Table I). Up to 11 years the frequency is about

TABLE I.—JUVENILE CIRRHOSIS (<21 YEARS)

| Type | History hepatitis: Yes | History hepatitis: No | Mean age | Male | Female |
|---|---|---|---|---|---|
| Relatively well; Acne, jaundice, S. globulins raised, &c. .. .. .. | 8 | 12 | 15 (9–21) | 3 | 17 |
| Other .. .. .. .. | 8 | 12 | 7 (2–12) | 8 | 12 |

the same (7 boys and 10 girls) but over 10 years and up to 16 the sufferers are predominantly female (2 males, 12 females). Waldenström (1950) drew attention to this type of cirrhosis in young women and it has since been described by Bearn *et al.* (1956). The patients are well-nourished with amenorrhœa, often acne, moon facies, pigmented striæ and rarely hirsuties.

These features suggest hyperadrenalism, and increased urinary corticoids have been found in some sufferers (Bongiovanni and Eisenmenger, 1951). Dr. R. I. S. Bayliss performed a hydrocortisone tolerance test in one patient and although the fasting blood 17-hydroxycorticosteroids were normal, tolerance was impaired. The patients are mildly jaundiced and serum bilirubin values rise at menstruation or after œstrogen administration (Bearn *et al.*, 1956).

The patients have febrile episodes, and sometimes polyarthritis of rheumatoid type. Serum gamma globulins are very high. A relationship to lupus erythematosus has been suggested for, very rarely, the L.E. phenomenon may be seen in the blood (Bearn *et al.*, 1956; Mackay *et al.*, 1956). Auto-immunization to liver cells has been suggested (Mackay *et al.*, 1956) and this is the rationale for steroid therapy. Prednisone is occasionally followed by a decrease in jaundice and a fall in serum globulins. Once started therapy may need to be continued for months or years.

In conclusion, I will state what I believe to be the indications for corticosteroid therapy in liver disease. Fulminant hepatitis proceeding to hepatic coma carries such a bad prognosis that intravenous hydrocortisone (200 mg. daily) should be given. By "buying time" hepatic regeneration may exceed degeneration. The type of virus hepatitis with prolonged jaundice of obstructive type (cholestasis) may be difficult to diagnose from extra-hepatic bile duct obstruction. In such circumstances, a profound fall in serum bilirubin levels after ACTH 40 units twice daily for four days suggests hepatitis (Shaldon and Sherlock, 1957). An indefinite fall is inconclusive. If the serum bilirubin level does decrease the ACTH should be replaced by prednisone and continued well into convalescence. Prolonged prednisone therapy is justified in cirrhotic patients with persistent jaundice and high serum gamma-globulins, on the supposition that the liver lesion might be due to auto-immunization, but there is no concrete evidence that the underlying liver disease is improved. Finally, a case can be made for using steroid therapy for patients with hepatitis in relapse.

*The Secretion of Neurohypophyseal Hormones in Man with Special Reference to Liver Disease*

An attempt has been made to investigate the secretion of neurohypophyseal hormones in man by assaying oxytocic and antidiuretic activity in blood. ADH is unstable in serum and it is now generally accepted that it is essential to use an intravenous technique for the assay of this hormone in body fluids (van Dyke *et al.*, 1955). Oxytocin can be assayed for its milk-ejecting activity in the lactating rabbit, but a more convenient preparation for routine work is the isolated uterus of the rat. It is not practicable, however, to use whole blood or plasma in an assay on an isolated organ because, when plasma comes into contact with glass or is diluted in the organ bath, active polypeptides are released from precursors in the plasma proteins. Other oxytocic substances are also present in blood such as potassium and 5-hydroxy-tryptamine.

In order to eliminate interfering substances and to obtain detectable amounts of activity, concentrated extracts were prepared from human blood by the method of Bisset and Walker (1954, 1957) or in recent work by a modification of that method (Bisset and Lee, 1957*a*). Oxytocic activity was assayed on the isolated uterus of the virgin rat in œstrus (Holton, 1948), and antidiuretic activity by intravenous injection of the extracts into rats under ethanol anæsthesia (Ames and van Dyke, 1952). Samples of the extracts were treated with 0·01 M sodium thioglycollate which inactivates neurohypophyseal hormones (van Dyke *et al.*, 1942). Any activity which was not abolished by this treatment was assumed to be due to an extraneous factor, and excluded from the results. Activity was assayed against oxytocin (Pitocin) or vasopressin (Pitressin).

In extracts of blood collected from the median cubital vein, under conditions of rest, antidiuretic activity was not detectable. Stimulating the neurohypophysis with nicotine was studied. A water diuresis was induced in a subject and then inhibited by smoking. To obtain an estimate of the amount of hormone released from the neurohypophysis, concentrated extracts were prepared from the urine by the method of Noble *et al.* (1939), according to the description given by Taylor and Walker (1951), and assayed for antidiuretic activity. Control experiments were carried out to estimate the recovery of ADH from the blood and from urine, and in order to correlate the results, suitable corrections have been applied to the assays. During the initial diuresis the concentration of antidiuretic activity in the peripheral venous blood was $<0{\cdot}008$ mU/ml. and the total amount excreted in the urine, 1·2 mU. During the period of antidiuresis the corresponding figures were 0·040 mU/ml. and 57 mU. There was no change in the oxytocic activity of the blood before and after smoking. It was found by Noble and Taylor (1953) that when ADH was infused intravenously in man, the mean excretion of hormone in the urine was approximately 13% of the amount infused. Conversely, if 57 mU were excreted in the urine in this experiment it may be assumed that the amount secreted by the neurohypophysis was of the order of 500 mU. Even if this amount were released instantaneously, the concentration in the blood alone could not exceed 0·1 mU/ml. The value actually obtained was 0·040 mU/ml., and this suggested that nicotine did in fact cause the sudden release of a large amount of ADH from the neurohypophysis. Further evidence for this view was obtained from another experiment in which antidiuretic activity was assayed in specimens of urine passed at intervals of fifteen minutes. It is evident from these experiments that, even when a powerful stimulus is applied to the neurohypophysis, the concentration of antidiuretic activity in the blood shows only a transient rise to detectable levels.

Ames *et al.* (1950) were unable to detect antidiuretic activity in blood from the femoral vein of dogs in which the neurohypophysis was stimulated by the intracarotid injection of hypertonic saline, but found that the concentration in blood from the internal jugular vein was as high as 0·5 mU/ml. It was, therefore, decided to assay activity in blood from the internal jugular vein in man. This was done in 11 patients under anæsthesia, prior to surgical operations (Bisset *et al.*, 1956). In control experiments, in which Pitocin or Pitressin was added to blood and extracted, approximately one-third of the activity was recovered. The figures which follow are not corrected for loss of activity on extraction. In 7 cases, the levels

of oxytocic activity were between 1·1 mU/ml. and 2·3 mU/ml., and in 4, antidiuretic activity was detected at levels between 0·012 mU/ml. and 0·025 mU/ml. It seemed possible that these comparatively high levels of activity might have been due to stimulation of the neurohypophysis by anæsthetic drugs.

Through the courtesy of Dr. Sheila Sherlock, it became possible to obtain blood samples from the internal jugular veins of conscious patients, who were undergoing cardiac catheterization as part of a procedure to investigate liver function. At the same time blood was taken from the femoral artery or the median cubital vein. A preliminary series of 6 cases has already been reported (Bisset and Lee, 1957*b*). The number has now been extended to 13. An improved method of extraction was used in these experiments (Bisset and Lee, 1957*b*). The average recovery was 58%. The figures which follow are uncorrected. The mean concentrations of oxytocic and antidiuretic activity in blood from the median cubital vein or the femoral artery were <0·4 mU/ml. and <0·006 mU/ml. respectively; in blood from the internal jugular vein, <0·6 mU/ml. and <0·009 mU/ml. Antidiuretic activity was detected in 5 cases in blood from the internal jugular vein only; the concentrations ranged from 0·005 mU/ml. to 0·025 mU/ml. In 2 cases in which it was possible to make a comparison, the concentration of oxytocic activity in blood from the internal jugular vein was three to six times higher than in blood from the median cubital vein or the femoral artery. A ratio of 6:1 was also obtained in an anæsthetized patient, not recorded in this series. The relatively high concentration of both oxytocic and antidiuretic activities in blood from the internal jugular vein, suggests that these activities are, in fact, due to the hormones of the neurohypophysis.

In the 5 cases in which antidiuretic activity was detected, the patients had fluid retention. However, there were 2 cases with fluid retention without detectable levels of antidiuretic activity. In one the ascitic fluid contained malignant cells and in the other case the œdema was resolving.

From each of the 3 cases with detectable levels of antidiuretic activity, and also from the case with resolving œdema, a twenty-four-hour sample of urine was collected, of which 100 ml. were extracted and assayed for antidiuretic activity. The mean recovery in extractions from urine was 30%. Table I gives the results, which are not corrected for loss of

TABLE I.—LEVELS OF ANTIDIURETIC ACTIVITY IN BLOOD AND URINE

| Antidiuretic activity in blood mU/ml. | Antidiuretic activity in urine mU/100 ml. | Daily urine volume (ml.) | Total antidiuretic activity mU/24 hours |
|---|---|---|---|
| 0·020 | 4·8 | 750 | 36 |
| 0·012 | 2·8 | 900 | 25 |
| 0·005 | 2 | 550 | 11 |
| <0·003 | <1 | 2,200 | — |

Blood was obtained from the internal jugular vein.

activity on extraction. It is of interest to note the correlation between the concentration of antidiuretic activity in central blood and the total amount of antidiuretic activity excreted in the urine.

It is believed that the antidiuretic activity is due to ADH. The levels of oxytocic activity appear to be relatively high, but if the activity is not due to oxytocin, it must be due to some unknown physiological substance which is inactivated by thioglycollic acid. Further work is necessary to establish that the oxytocic activity is due to oxytocin.

**Dr. W. H. J. Summerskill** (London):

*Adrenal Steroids and the Liver*

(1) *The metabolism of steroids by the liver.*—With the exception of high levels of urinary aldosterone, especially with ascites, and low concentrations of 17-ketosteroids in the urine, the latter probably reflecting decreased production, there is little clinical or biochemical evidence of abnormal adrenal steroid metabolism in patients with liver disease under normal circumstances. However, infused hydrocortisone disappears more slowly than in the normal subject, impaired metabolism being related to the degree of liver damage in terms of bromsulphthalein retention (Plager *et al.*, 1954). The utilization of cortisone is normal in patients with liver disease, but a block is thought to occur in the enzymatic reduction of hydrocortisone to the tetra compounds (Brown, 1957). The inactivation of orally administered steroids in the liver is probably an important factor in explaining their lower potency in relation to systemic hydrocortisone or ACTH.

The metabolic processes involved in the degradation of aldosterone are unknown, but human liver slices inactivate the salt-retaining fraction from human urine (Chart *et al.*, 1956) and the liver is probably the site of its metabolism.

(2) *Steroid drugs and jaundice.*—The indications for steroid therapy in liver disease have been discussed by Dr. Sherlock, but their contribution to diagnosis should be emphasized as well. Solem and Olsen (1953) recommended the use of these drugs in icteric patients because of their effect in decreasing hepato-cellular jaundice as opposed to obstructive jaundice but Katz *et al.* (1957) showed that prednisone or corticotrophin reduced serum bilirubin values even in patients with extrahepatic obstructive jaundice. Urinary bilirubin excretion decreased simultaneously and, as there was no increase in fæcal bile or stercobilinogen, it appeared that the drugs delayed the breakdown of red cells or hæmoglobin rather than stimulating the excretion of bile by the liver.

Review of the literature shows that dramatic (50%) reduction in serum bilirubin levels within seven days of steroid or corticotrophin administration is frequent in patients with hepatitis, but relatively uncommon in extrahepatic obstructive jaundice. Its use therefore appears to have clinical application as a diagnostic test, despite its lack of biochemical specificity, and this is supported by recent experiences in 7 cases (Fig. 1) (Jones and Summerskill, 1958).

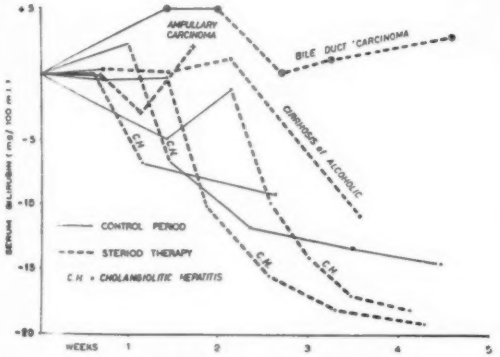

FIG. 1.—The effect of steroids on jaundice.

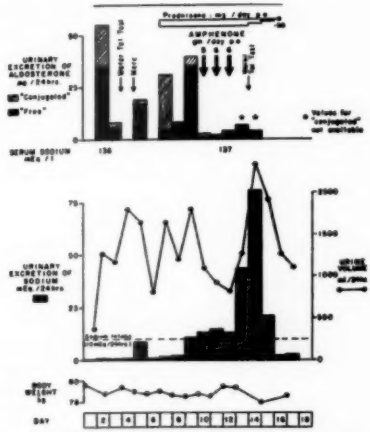

FIG. 2.—The effect of amphenone on urinary excretion of aldosterone and sodium in a patient with ascites.

In all patients the serum bilirubin level prior to treatment was above 12 mg./100 ml. and both clinical and biochemical evidence suggested obstruction. In 2 patients with extrahepatic obstruction, the response to steroid therapy was trivial and brief. A patient with cirrhosis showed no response for two weeks; then biochemical improvement, unrelated to clinical improvement, occurred. In contrast, 4 patients with "cholangiolitic" hepatitis showed an immediate response to steroid therapy. The fall in serum bilirubin levels progressed rapidly in 2 patients in whom treatment was continued, but biochemical improvement was slower after the drug was withdrawn in the other 2 patients. If, under such circumstances, treatment with steroids is continued, the less specific action of these drugs (improvement in appetite

and subjective well-being with decrease in jaundice not fully related to histological improvement in the liver) demands their cautious withdrawal during the apparent recovery phase in case relapses occur.

(3) *Ascites.*—The theoretical pathogenesis of ascites is compounded of several factors, but which are causal and which are secondary effects is not clear. Potentially the most important influence in maintaining the ascitic state is renal conservation of sodium and water. Of the hormones metabolized by the liver and capable of contributing to this mechanism, aldosterone, A.D.H. and possibly œstrogens deserve special consideration.

High levels of urinary aldosterone occur in patients with liver disease, especially in the presence of ascites, and the unconjugated portion of aldosterone is excessive, perhaps reflecting impaired hepatic function. A direct approach to the relationship between ascites and adrenal function by bilateral adrenalectomy has been utilized on individual patients by Marson (1954) and Giuseffi *et al.* (1957). Both patients had an immediate sodium diuresis after operation, but improvement in the ascites was much slower and symptoms of adrenal insufficiency followed, particularly sodium depletion in excess of that found in patients undergoing adrenalectomy for other diseases. Ascites re-accumulated unless careful control was exercised over dietary sodium and steroid maintenance. Mercurial diuretics, previously ineffective, secured an effective sodium diuresis after operation. Both patients finally lost their ascites but its tendency to re-accumulate shows that extra-adrenal factors are also important in the sodium and water retention of liver disease.

Summerskill and Crabbé (1957) used Amphenone, a drug which inhibits aldosterone secretion, in 4 patients with ascites complicating cirrhosis. In 2 patients whose ascites responded to bed rest, sodium restriction and mercurial diuretics, there was no increase in sodium excretion, despite the reduction of urinary aldosterone levels to the normal range. In contrast, 2 patients who were resistant to routine management had impressive sodium diuresis, urinary sodium levels rising from less than 1 mEq. to 60–80 mEq. in twenty-four hours. Urine aldosterone levels, previously abnormally high, fell to within the normal range when Amphenone was given (Fig. 2). In both these subjects impending hepatic coma occurred and disappeared when the drug was withdrawn. This and other toxic reactions constitute a great disadvantage to Amphenone therapy. The patients also received prednisone and in one patient a small sodium diuresis (<10 mEq. in twenty-four hours) occurred (Fig. 2), apparently in response to steroid therapy. Similar responses in patients with ascites have been reported (Muller *et al.*, 1956) but they are unusual and difficult to explain. There was no alteration in urinary aldosterone levels during prednisone therapy in these patients.

The terminal phase of ascites in the absence of other complications is one of progressive hypotension, oliguria, hyponatræmia and avid water retention. Although these symptoms suggest sodium depletion, the infusion of 200 ml. of 5% sodium chloride effected no clinical or biochemical improvement in 7 patients, which is in accord with the observations of others. The prognosis at this stage is very poor and it is uncertain whether hyperaldosteronism contributes significantly to the syndrome, although increased antidiuretic hormone activity could explain it.

Factors related to liver function, including low serum albumin levels and the impaired metabolism of aldosterone and other hormones, are probably important in all phases of ascites formation. Portal hypertension appears to influence the site of fluid collection as well as contributing to its accumulation. Hyperaldosteronism seems to be clinically related to the more advanced phase of resistance to diuretics, as adrenalectomy re-establishes sensitivity to diuretics with loss of the ascites. Nevertheless, as sodium and water can still accumulate under these circumstances, extra-adrenal factors, including neurohypophyseal function and increased œstrogen activity, have to be considered.

ACKNOWLEDGMENT.—I am grateful to the Editor of the *Lancet* for permission to reproduce Fig. 2.

# Clinical Section

President—E. W. RICHES, M.C., M.S., F.R.C.S.

[*February* 14, 1958]

MEETING AT THE MIDDLESEX HOSPITAL, LONDON

**Hypophysectomy for Incipient Blindness Due to Progressive Diabetic Retinopathy.**—J. D. H. SLATER, M.B., M.R.C.P. (for J. D. N. NABARRO, M.D., F.R.C.P.).

*History.*—Mr. N. H., aged 33, had had diabetes mellitus since the age of 9. From puberty, control of his diabetes had been difficult owing to his large and fluctuating insulin requirement (80–200 units daily, but reaching 350 units daily in 1943). Diabetic retinopathy was first recognized on routine examination in 1950. Since early 1956 his eyesight had been failing rapidly due to recurrent vitreous hæmorrhages. In the spring of 1957 he became blind in the right eye and until his operation was unable to read with the left eye. Mild proteinuria and mild neuropathy had been present since 1953.

*Pre-operatively* he required 64 units of soluble insulin in two doses with a diet containing 125 grams of carbohydrate. The blood pressure was 150/90 and his weight 12 st. 9 lb. Renal function studies showed a glomerular filtration rate (inulin clearance) of 108 ml. per minute, the blood urea was 29 mg./100 ml., and the urine deposit normal. The serum cholesterol was 310 mg./100 ml. Ophthalmoscopic examination revealed an extensive retinal detachment on the right and retinitis proliferans with retinal hæmorrhages on the left (Mr. Derek Ainslie).

*October* 1957: Hypophysectomy was carried out by Mr. Valentine Logue. This was technically difficult but appeared complete; Zenker's solution was used.

*February* 1958: His diabetes mellitus is well controlled with a reduced insulin dose (48 units soluble insulin daily) despite an extra 50 grams of carbohydrate daily. He feels well and is back at work as sales manager of a large concern. He takes cortisone 15 mg. daily, tri-iodothyronine 40 $\mu$g. daily and Pitressin Tannate 10 units i.m. every three to four days as replacement therapy. He is able to read small print with a magnifying glass although two further small vitreous hæmorrhages have occurred since his hypophysectomy. Complete removal of all functioning pituitary tissue is indicated by the development of myxœdema five and a half weeks post-operatively, the twenty-four-hour neck uptake of radio-active iodine falling from 26% to less than 4%.

**Dr. Nabarro:** Late complications affecting the blood vessels, kidneys and retina are becoming increasingly important in juvenile diabetics. Once retinitis proliferans has developed it usually progresses rapidly to total blindness and little can be done to prevent this disastrous complication. In 1953, Poulsen reported a patient in whom progressive diabetic retinitis had been arrested following the occurrence of pituitary necrosis. Luft and Olivecrona (Luft *et al.*, 1955) subsequently performed total hypophysectomy in a series of diabetics with severe retinitis and there seems to be little doubt that some patients were improved.

Three points require special emphasis. Hypophysectomy must be complete if lasting benefit is to be achieved; in contrast patients with widespread breast cancer may be greatly improved after partial or incomplete hypophysectomy. Post-operative complications are more common in diabetics than in cancer patients undergoing hypophysectomy; this is probably due to the arterial changes of long-standing diabetes. Thirdly, the management of the diabetes presents a number of special difficulties in the early post-operative period.

At the Middlesex Hospital 3 patients have had hypophysectomy performed for progressive diabetic retinitis. One died seven days after the operation. It is too early to claim that blindness has been prevented by the operation in the other 2, although there are signs that the retinitis is less active. The reason for showing this patient is to demonstrate that hypophysectomized young diabetics can be maintained in satisfactory health and are able to lead an active life.

**Sensory Nerve Conduction after Traction Lesion of the Brachial Plexus.**—GEORGE BONNEY, M.S., F.R.C.S., and R. W. GILLIATT, D.M., M.R.C.P.

Failure of recovery after a complete supraclavicular traction injury of the brachial plexus is often due to avulsion of nerve roots from the spinal cord. The lesion of the posterior roots is between the posterior root ganglion and the cord, and consequently the peripheral axons of this root do not undergo degeneration. Previous work (Bonney, 1954) has shown

that under these circumstances axon responses can be produced in the skin supplied by the affected nerve, long after the period required for axonal degeneration. The examination of these responses is a valuable guide to the placing of the lesion. In the present case it has been possible to provide additional proof of the integrity of the peripheral axons, by the demonstration of afferent impulses in the nerves of a limb paralysed by a traction lesion of the brachial plexus.

*Case History* (Patient referred by Mr. K. I. Nissen)

P. D. H., a man aged 24, was involved in a motor cycle accident on October 19, 1957, and sustained a traction lesion of the right brachial plexus. The initial examination showed complete flaccid paralysis of the muscles of the right arm and shoulder girdle with sparing of trapezius and rhomboids and partial sparing of serratus anterior. There was complete sensory loss over the dermatomes C.5 to T.1, with patchy sensory loss over the dermatomes C.3 and C.4. There was a right Horner's syndrome, and the skin of the right upper limb was dry. Screening showed normal diaphragmatic movements. The paralysis was unchanged in February 1958, by which time there was considerable wasting of the affected muscles.

*Investigations.*—Strength-duration curves (22.1.58) of representative muscles showed reaction of degeneration. Vasomotor responses (22.1.58): Resting skin temperature of digits of affected hand 24·5° C. No response to fifteen minutes' heating of the healthy hand and forearm. Electromyography (15.1.58): Right thenar muscles explored with needle electrode. Profuse fibrillation but no motor unit activity. Electrical stimulation of median nerve trunk at the wrist with brief shocks produced no electrical or clinical response from the thenar muscles.

FIG. 1.—Response to intradermal histamine on radial and ulnar sides of affected forearm.

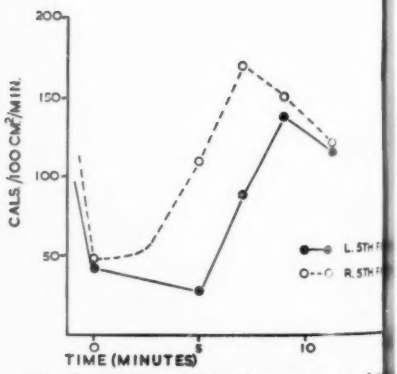

FIG. 2.—Cold vasodilatation response of fi fingers of healthy (left) and affected (right) ha compared.

*Axon responses* (25.11.57 and 22.1.58).—Response to intradermal injection of histamine was normal on the ulnar aspect of the forearm but on the radial aspect was that of axonal degeneration (Fig. 1). The cold vasodilatation response of the second and fifth digits was similar to that shown by these digits on the healthy side (Fig. 2).

*Demonstration of afferent impulses* (15.1.58).—The method of direct recording from sensory nerve trunks described by Gilliatt and Sears (1958) was used. Sensory action potentials were recorded without difficulty from the median and ulnar nerves at the wrist on both sides (Fig. 3). Stimulus intensities and the positions of stimulating and recording electrodes were the same in the two arms. Although the potentials on the affected side were slightly smaller in amplitude than those recorded from the opposite arm, their latency was not significantly increased.

*Discussion.*—In this case there was clinical evidence of a complete degenerative supraclavicular lesion of the brachial plexus. The sparing of the rhomboids and of part of

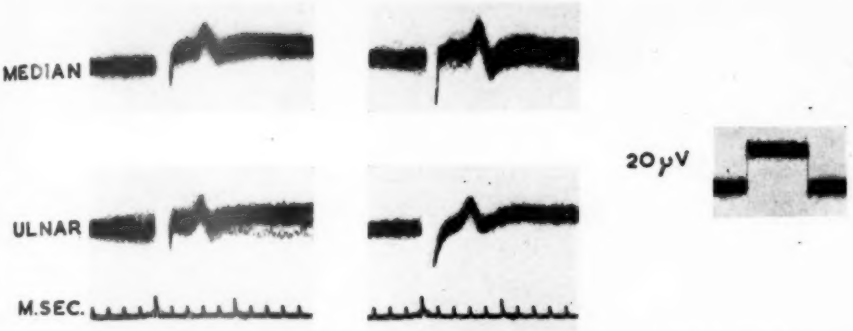

FIG. 3.—Records from median and ulnar nerves at the wrist during stimulation of index and little fingers respectively. Tracing shows stimulus artefact followed by nerve action potential. In each case twenty sweeps superimposed.

serratus anterior suggested that the lesion of the V cervical nerve was distal to the intervertebral foramen, but no further evidence as to the placing of the lesion was available from clinical examination or from the usual investigations. The finding of normal axon responses in the second and fifth digits and on the ulnar aspect of the forearm suggested that for the axons in the VII and VIII cervical and I thoracic nerves mediating these responses, the lesion was proximal to the posterior root ganglion. The demonstration of afferent volleys in the nerves of the affected arm showed that this was true also for the large fast-conducting axons in these nerves. These findings are of special interest in that they show almost normal electrical activity in nerves detached from the spinal cord. They are of some practical importance in assessing prognosis.

**Traumatic, Right-sided, Diaphragmatic Hernia: a Mistake in Diagnosis.**—J. K. ROSS, F.R.C.S., and L. P. Le QUESNE, D.M., F.R.C.S.

In August 1956 Mr. T. S., a taxi-driver, was admitted to the Middlesex Hospital for surgical treatment of a chronic duodenal ulcer. He gave a sixteen-year history of dyspepsia. Five years previously he had had a course of in-patient medical treatment with little benefit, and repeated barium meals had shown a distorted, deformed cap, though a crater had never been clearly demonstrated. X-rays of the chest before operation showed, as on previous occasions, opacity at the right base, reported as old basal pleurisy.

On 22.8.56 the abdomen was opened through a mid-line epigastric incision. The stomach and transverse colon were found stretched tightly across the posterior abdominal wall and could not be delivered. The stomach was traced to the right and the pyloric portion was found to pass, together with the hepatic flexure of the colon, behind the right lobe of the liver, up into the chest through a 3 in. hole in the diaphragm. Neither viscus could be withdrawn into the abdomen, which was accordingly closed.

On going into the patient's history again after this operation it was found that his symptoms began in 1941, whilst in hospital recovering from injuries received when his house was wrecked by a bomb. He himself was buried up to his clavicles in fallen masonry for seven hours, incurring fractures of his right leg and of his 4 lower right ribs. At first his indigestion was ascribed to "nerves", but later, following a barium meal, to a duodenal ulcer for which he was treated for fifteen years. Throughout this time his symptoms were continuous rather than intermittent. Though he complained of post-prandial pain, this tended to be in the lower right chest rather than epigastric and his predominant complaint was of repeated vomiting of small quantities after meals. Further, he stated that he had had no relief from his symptoms whilst in hospital on a strict ulcer regime.

A retrospective examination of his various X-rays revealed that the pyloric portion of the stomach and duodenal cap lay unduly high and that the deformity was really due to external distortion (Fig. 1). Further, it could be seen that the opacity at the right lung base contained a few gas shadows, obviously in displaced colon. Whilst he was recovering from the laparotomy a barium enema was performed and this clearly showed colon above the diaphragm in the right thorax (Fig. 2).

On 5.9.56 the right chest was opened through the bed of the 9th rib. The hepatic flexure

FIG. 1.

FIG. 2.

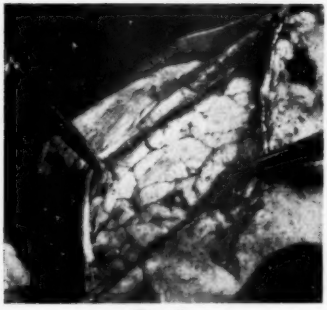

FIG. 3.

FIG. 1.—Barium meal film, showing the high, transverse position of the stomach, and the deformity of the pylorus and duodenum probably caused by external pressure from the margins of the diaphragmatic defect.

FIG. 2.—Barium enema film, showing the hepatic flexure of the colon lying in the right hemithorax.

FIG. 3.—Photograph showing the rent in the diaphragm. The hernia has been reduced and omentum can be seen through the defect. The lung is seen in the lower left corner of the picture.

of the colon, the pylorus, proximal duodenum and a mass of omentum were found lying free in the pleural cavity. They had passed through a split in the postero-lateral portion of the diaphragm and were lightly adherent to its margins. The split was oval in shape and had firm, fibrous edges (Fig. 3): postero-laterally it extended to within 2 in. of the costophrenic sulcus and antero-medially encroached on the central tendon. There was no duodenal ulcer. The viscera were returned to the abdomen, the defect closed with interrupted linen sutures and the chest closed. Recovery from this operation was uneventful.

Apart from its comparative rarity, the case is interesting because it demonstrates forcibly the great difficulty in reviewing a case afresh when once a diagnosis has been made, supported by a firm radiological report. Apart from the mode of onset, it is clear in retrospect that this man's symptoms were not typical of a duodenal ulcer; the absence of remissions and the failure of treatment to give relief were quite unlike the usual ulcer history. These features should have led to a questioning of the diagnosis, and probably would have done so had it not been for the repeated radiological reports of a duodenal ulcer. This patient's story clearly emphasizes yet again the importance of taking an accurate history and of questioning the results of ancillary methods of diagnosis if their results are at variance with the clinical picture.

The facts which distinguish the hernia in the case here presented from one of congenital origin are:

(1) The clear history of trauma.
(2) The absence of a hernial sac.
(3) The presence of adhesions at the margins of the defect.
(4) The fact that the aperture was not in the position of a recognized congenital defect.

Rupture of the right hemi-diaphragm due to closed injury with herniation of abdominal viscera into the right side of the chest is uncommon owing to the presence of the liver, which tends to plug, and therefore mask, small rents in the right diaphragm. The defect may only become apparent if the liver is ruptured and a right hæmothorax develops.

Closed injury can produce tears in the diaphragm in two ways. There may be a "burst" type of injury, the compressing force being transmitted to the stretched diaphragm by the upper abdominal viscera. This is said to be more common in the younger age groups, whose lower thoracic cage is more supple. Alternatively the diaphragm may be lacerated by fractured ribs and this would seem to be the mechanism involved in the present case.

Viscera which have been found displaced into the right side of the chest in reported cases include the liver and gall-bladder, transverse and ascending colon and cæcum, stomach, duodenum, omentum, small intestine and, in one instance, the pancreas. In the great majority of recorded cases the liver itself had become herniated into the chest, and in this respect the present case is of interest in that no part of the liver had passed through what was a relatively small defect.

**Renal Tuberculosis. Ileocystoplasty.**—E. W. RICHES, M.C., M.S., F.R.C.S.

Male aged 32.

*History.*—In 1947 he was invalided from the R.A.F. for a tuberculous pleural effusion. In February 1954 he had hæmaturia, increased frequency and pain in the right loin; acid-alcohol-fast bacilli were found in the urine. There was tuberculous cystitis and excretion and retrograde pyelograms showed an early tuberculous lesion of the right kidney (Fig. 1). Treatment with streptomycin (1 gram daily) and isoniazid (200 mg. daily) was started.

*Progress.*—His symptoms disappeared but in April 1955 the urine was again positive for tubercle bacilli. Domiciliary treatment was continued with PAS 12 grams daily and alternating three-monthly courses of streptomycin 1 gram twice weekly and isoniazid 100 mg. daily. By November 1956 he was symptom-free but the condition of the bladder had deteriorated and there was now more dilatation of the right lower calyx and some obstruction in the upper ureter (Fig. 2). The urine gave a positive culture for tubercle bacilli. By September 1957 he was micturating six times at night; the bladder held only 2 oz. (57 ml.). Excretion pyelography showed no excretion from the right kidney but hydro-ureter and hydronephrosis on the left (Fig. 3). There was reflux up the left ureter on cystography (Fig. 4): blood urea 39 mg. per 100 ml.

On October 11, 1957, ileocystoplasty was performed after the method of Yeates (1956) but with drastic resection of the rigid bladder dome. The left ureter was reimplanted over a polythene tube into the ileal graft; the thickened right ureter was divided and exteriorized pending right nephro-ureterectomy which was done six weeks later. The right kidney showed advanced renal tuberculosis with very little activity.

FIG. 1.—Retrograde pyelogram, February 1954, showing some dilatation of the right lower calyx and a little erosion. Left side normal.

FIG. 2.—Retrograde pyelogram, November 1956, showing narrowing of the right upper ureter and further dilatation of the lower calyx.

FIG. 3.—Excretion pyelogram, September 1957, showing left hydronephrosis and hydro-ureter with no excretion on the right.

FIG. 4.—Cystogram, October 1957. The bladder is contracted and there is reflux up the dilated left ureter.

FIG. 5.—Excretion pyelogram, February 1958. The function of the left kidney is good, and it has returned to normal size.

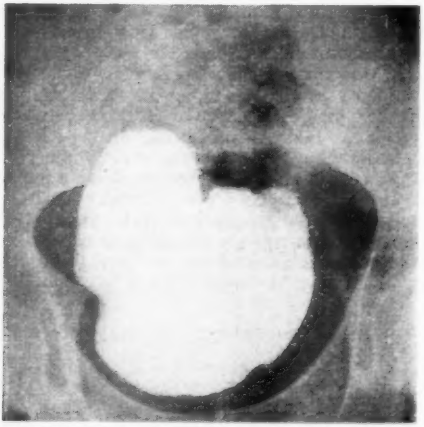

FIG. 6.—Cystogram. February 1958. The bladder held 20 oz. (568 ml.) without discomfort. There is no ureteric reflux.

*Result.*—In February 1958 he was much improved. He urinated only once per night, and he had been able to hold as much as 20 oz. He had gained 8 lb. in weight: blood urea 44 mg. per 100 ml. Excretion pyelography showed good function in the left kidney (Fig. 5) with minimal residual urine.

A cystogram showed a large bladder with no ureteric reflux (Fig. 6). No tubercle bacilli were found in the urine. Anti-tuberculous chemotherapy is being continued.

## BOOK REVIEWS

**The Eye in General Practice.** By C. R. S. Jackson, M.A., B.M., B.Ch.Oxon., D.O.M.S., F.R.C.S.Ed. (Pp. viii+152; illustrated. 21s. 0d.) Edinburgh and London: E. & S. Livingstone Ltd. 1957.

This is an excellent book and was recommended at the discussion at the General Practice Section Meeting at the Royal Society of Medicine on the subject of "Eyes in General Practice" in April 1957.

The book describes clearly how to examine the eye with a loupe and a focusing torch. The reviewer has often seen postgraduate students who have a good knowledge of the use of the ophthalmoscope and of the abnormal retinal conditions but who cannot examine the cornea or the iris.

The modern treatment of inflammatory conditions of the eye with corticosteroids (cortisone and hydrocortisone) demands a careful examination of the anterior segment of the eye to exclude iritis or iridocyclitis. This book is up to date because it clearly indicates under which conditions cortisone or hydrocortisone should be used. Not enough stress is laid, however, on the necessity for the use of cortisone or hydrocortisone in the treatment of iritis and iridocyclitis.

In the chapter on Choroiditis the author mentions that cortisone or other corticosteroids are now being used. Most ophthalmologists now agree that in cases of severe choroiditis systemic corticosteroids (cortisone, hydrocortisone, prednisone and prednisolone) are essential.

The chapter on squint and its treatment is good. The author advises that the squinting child should be treated with glasses, occlusion of the good eye, and orthoptics, before operative measures are resorted to. Reviews in various eye clinics have shown that operative treatment is best carried out at a very early age.

**Aortography. Its Application in Urological and Some Other Conditions.** By W. Barr Stirling, Ch.M., F.R.C.S.Ed., F.R.F.P.S.G. (Pp. vii+292; illustrated; 50s. 0d.) Edinburgh and London: Livingstone. 1957.

This monograph, based on the author's personal experience of some 500 aortograms, contains certain hitherto unpublished work and is a valuable contribution to both urology and radiology. The book is well assembled, the early chapters describing in detail the history, surgical anatomy, technique and potential hazards and complications of aortography. An interesting chapter is devoted to experimental work on pressure factors during injection of the dye.

In the author's hands aortography with modern contrast media is a comparatively safe procedure and his experience should help to reassure those urologists and surgeons who are still reluctant to use this diagnostic adjunct.

Mr. Stirling has devised a mechanical pressure injector which delivers 15 ml. of dye in less than one second and is connected electrically with the X-ray control table. At a time when retrograde catheterization of the aorta is gaining favour, he confidently advocates percutaneous puncture and finds his method simple, quick and free from serious hazard.

The second half of the book is devoted to the applications of aortography. Naturally most of the work is concerned with renal conditions. Some of the aortograms performed appear superfluous for not everyone will agree that aortography should be an essential investigation in all cases of congenital renal anomaly where surgery is contemplated.

There are useful sections on vesical neoplasm, disease in other abdominal viscera and bone tumour and the final chapter deals with intrinsic vascular disease giving a description of the technique of low aortography and of various aortic and peripheral vascular disorders. A striking feature is the very high quality of the abundant reproductions.

**Surgery: Principles and Practice.** Ed. by J. Garrott Allen, M.D., Henry N. Harkins, M.D., Ph.D., Carl A. Moyer, M.D., and Jonathan E. Rhoads, M.D., D.Sc.(Med.). (Pp. xxii+1495; illustrated; £5 10s. 0d.) London: Pitman. 1957.

This is the most exciting new textbook of surgery to appear since the war and presents a comprehensive and quite admirable exposition of the best in American surgical teaching at the present day.

The authors are well known to many people in this country and represent four widely separate university surgical centres in North America. Their average age is 45 and they bring

a freshness and enthusiasm to the task which makes the book a joy to read. They have co-opted a group of surgeons, each well known in his own particular field, and have then taken all these sections and welded them into what is a first-class introduction to general surgery. The book is new in every sense of the word and its foundations are physiology and pathology; these of course are the most solid foundations such a textbook could have, for it is from them that most new advances have come and it is also from them that a proper understanding of surgical practice arises.

It is unusual to find a textbook designed primarily for undergraduates with references at the end of each chapter, but these references are very well chosen, and if they do guide the student to start reading for himself in the original literature they will have been a worth-while innovation. Diseases of the endocrine system and the cardiovascular system occupy a very large part of the work whereas it is hard to find any kind of mention of amputations which, of course, will still need to be practised although they used to form far too large a part of the older textbooks. The illustrations are excellent. The photographs have only been included because they demonstrate something and the X-rays are well explained and for the most part extremely clear.

The printing and format of the book leave nothing to be desired; the double column pages are restful for reading and the type-face used is clear and attractive. It would surely be an advantage to bring this work out in future in two volumes since the present single one is much too bulky to hold comfortably and it is unlikely that the binding will long stand up to the wear which it should receive.

**Studies on Fertility.** Including papers read at the Conference of the Society for the Study of Fertility, London, 1956. Being Volume VIII of the Proceedings of the Society. Edited by R. G. Harrison, M.A., D.M. (Pp. x+138; illustrated; 25s.) Oxford: Blackwell Scientific Publications. 1957.

This excellent and carefully selected collection of thirteen papers, the eighth of such annual volumes to be produced, is largely devoted to male fertility problems. Current research on infertility rightly relies considerably on animal experiment, to which seven papers are devoted. The first paper by Mrs. C. Harvey on partitioned ejaculates emphasizes a finding of the utmost practical importance—the vastly increased sperm density in the first 0·5–1·0 ml. of semen ejaculated. In a later section, Mrs. M. C. N. Jackson rightly stresses the great advantages of using the split specimen technique of artificial insemination for cases of oligozoospermia. Hanley reports a technical triumph in epididymal surgery—the formation of spermatocele or cyst from which sperms were aspirated and inseminated with a resulting and successful pregnancy. There is an interesting paper from Liverpool on thermo-regulation of the testes emphasizing the effective radiator role of the scrotum.

One of the few sections on female infertility introduces a new long-acting progestational compound, 17-AHPC. It is highly potent and relatively free from side-effects. It is naturally vaunted for habitual abortion! Following a brief mention of low dosage pituitary irradiation the book ends appropriately with the effects of X-irradiation of the testes of mice. A stimulating and important book for the expert.

**Salmonellosis in Animals.** A Review. Review Series No. 5 of the Commonwealth Bureau of Animal Health. By A. Buxton, Ph.D., M.R.C.V.S. (Pp. vi+209; 25s. 0d.) Farnham Royal, Bucks: Commonwealth Agricultural Bureaux. 1957.

There was no up-to-date account of salmonella infection in animals and the author is to be congratulated on filling a much-wanted need. He has devoted a good many years to the study of salmonella organisms and is well qualified for the task.

The eight chapters of the book deal with: General Characters of the Salmonellæ; Classification; The Distribution of Salmonella Serotypes among Animals; Symptoms and Lesions of infection; Epidemiology; Immunology; Antibacterial Substances; and Public Health Aspects of Salmonella Infections. In addition there is a bibliography of over 1,500 selected references.

A great merit of this book is that the bacteriology and immunology are according to conventional teaching in the sense that they are based closely on the agreed systems used by the outstanding authorities in Denmark, Britain and the United States. It is impossible to write comprehensively about salmonella organisms without the use of tables and all the essential data are given in this form where possible. Among others is a most useful one covering several pages which shows the host species from which each salmonella serotype has been isolated. It includes the author references for each.

Even on a subject on which currently there is such a voluminous literature this book is unique in the cover it gives.

**Chronic Bronchitis, Emphysema and Cor Pulmonale.** By C. H. Stuart-Harris, M.D.Lond., F.R.C.P., and T. Hanley, M.D.Lond., M.R.C.P. (Pp. v+252; illustrated. 42s. 0d.) Bristol: John Wright & Sons Ltd. 1957.

This monograph, written as a record of the successive pieces of research carried out by the staff of the Department of Medicine of the University of Sheffield in the past ten years, deals successfully with the natural history and clinical patterns of bronchitis and is an invaluable guide to the family doctor who is overwhelmed with this type of case during the epidemic season. A valuable aspect of the work is found in the field studies on the epidemiology of this disease. The clinical picture, the problems in differential diagnosis, the significance of infection, emphysema and pulmonary heart disease, are all carefully considered.

Some contradictions occur with regard to the indications for antibiotic therapy. The presence of a purulent sputum is in one part of the book considered unreliable whereas elsewhere it is regarded as an index for modern antibiotic treatment.

Notwithstanding minor criticisms, the book is a model of its kind, admirably produced, and a worth-while addition to the ever-increasing literature on this subject.

**Medicine. Essentials for Practitioners and Students.** By G. E. Beaumont, M.A., D.M., F.R.C.P., D.P.H. 7th edition. (Pp. xviii+847; illustrated. 45s. 0d.) London: Churchill. 1958.

This well-known textbook of medicine, first published in 1932, has achieved the distinction of reaching its seventh edition this year. It has been translated into Italian and Spanish and is an invaluable compendium of medical practice. For the student, for whom it is primarily intended, it summarizes the essentials of medicine, eschewing all superfluous detail. It should also be extremely valuable to the family practitioner.

It is remarkable to find the whole of endocrinology and neurology, the cardiovascular, respiratory and alimentary systems, and tropical diseases, to name only a few, all succinctly summarized and the most recent advances touched upon—all from the pen of one man.

In this seventh volume the author has, however, permitted himself one departure from his normal practice: he has allowed a very good chapter on water and electrolytic balance to be contributed by his former registrar, Dr. P. H. Friedlander.

One or two minor criticisms should perhaps be made: it is questionable whether "disseminated" lupus erythematosus should be classified under "The Joints" for many other systems are, as Dr. Beaumont points out, involved. "Systemic" is, incidentally, a more accurate term than "disseminated". A special chapter on The Collagen Diseases would have been more in line with modern trends and polyarteritis nodosa, systemic lupus erythematosus, scleroderma and dermatomyositis could then have been integrated in such a chapter.

**Combined Textbook; Obstetrics and Gynæcology.** Edited by Dugald Baird, B.Sc., M.D., D.P.H., F.R.C.O.G. (Pp. xii+936; illustrated; 95s.) Edinburgh and London: Livingstone. 1957.

The 1957 edition of this popular textbook has been reduced in size from 1,411 to 936 pages and the editor hopes that the edition will be "more convenient to handle". Doubtless Professor J. M. Munro Kerr, who was responsible for the first four editions and who contributed to the fifth, will whole-heartedly approve. Much of the value lies in the excellent vital statistics which have been such a feature of Professor Baird's publications in recent years. Most sections are followed by references but it was disappointing that there was no reference to the work of Sutherland and Barnes on pelvic tuberculosis. The proof readers had failed to correct the dosages for streptomycin and PAS. It was surprising that in the section on heart disease Macrae's carefully documented publications are not mentioned, nor the classification of the American Heart Association. The Drew Smythe catheter was designed to preserve the forewaters and prevent intra-uterine sepsis—not prolapse of the cord. Air embolus occurs with an air insufflator (Fig. 438); only carbon dioxide should be used and only after biopsy and culture of the endometrium to exclude pelvic tuberculosis. In the operation of presacral neurectomy, a para-umbilical incision is an advantage and the ureters and left common iliac vein identified and thus avoided. In the chapter on antepartum hæmorrhage it is encouraging to read "that even in the absence of any history of hæmorrhage, routine ante-natal examination of the abdomen may reveal signs suggestive of placenta prævia".

The above are minor criticisms of an excellent textbook to which seventeen authors have contributed.

**The Pathology and Surgery of the Veins of the Lower Limb.** By Harold Dodd, Ch.M., F.R.C.S., and Frank B. Cockett, M.S., F.R.C.S. (Pp. ix+462; illustrated. 65s. net.) Edinburgh and London: E. & S. Livingstone Ltd. 1956.

The authors of this book have performed a great service in making the new knowledge on the venous system of the lower limb available in an easily assimilable form. The reader will be stimulated to review and to improve his approach to the surgical management of conditions which so greatly affect the "comfort and activity of mankind".

Operative treatment of varicose veins and ulcers is described with a clarity and wealth of detail from which not only the "young trainee surgeon" but his experienced elders as well cannot fail to improve their technique.

A notable feature of this book is the attention devoted to conservative treatment and post-operative management, for pre-eminently this is a field of surgery in which the operation is but an incident in the course of treatment.

For the treatment of varicose veins and venous ulcers much experience is needed to select the best method for the particular patient. The balanced sections on indications and contra-indications will restrain those junior surgeons, who inevitably lack this experience, from the temptation of performing all the operations on all the patients.

The illustrations are excellent.

**Operative Surgery.** Edited by Charles Rob, M.D., M.Chir., F.R.C.S., and Rodney Smith, M.S., F.R.C.S. Volume 5. Orthopædic Surgery. (Pp. xiii+366+5; illustrated; £5 10s.) London: Butterworth. 1957.

This volume maintains the standard of the previous volumes already reviewed in these columns. It will probably prove most useful to the non-orthopædic surgeon when faced with the simpler types of operation such as for hallux valgus, hammer toe, in-growing toe nail, or removal of a semilunar cartilage. The more complicated operations are an imposing record of orthopædic skill and achievement.

**A Primer of Pædiatrics for the Senior Student and Family Doctor.** By E. Hinden, M.D.Camb., M.R.C.P.Lond. (Pp. xv+356; 25s.) London: Macdonald & Co. (Publishers) Ltd. 1957.

The author, in his preface, sets out the purpose of this book: "To deal with the common things the family doctor will encounter in his young patients, and to help him to manage them." The book is in three sections: (1) From conception to 4 weeks of age; (2) From 4 weeks to 2 years; (3) From 2 years to puberty. It is delightfully written and the author always ends each chapter by stating his own opinion based on current knowledge of the problem.

The opening chapter on "The Child's Heredity" is excellent and he goes so far as to define the "genes", so that the simple explanation of a defective gene leading to a dominant trait, and the defective recessive gene only giving rise to symptoms when it is present in both parents, is easily understood.

Section (2), from 4 weeks to 2 years, deals with normal growth during that period and then deals with the diseases of the various systems occurring in that period. The descriptions are full, adequate and stimulating. In Section (3), from 2 years to puberty, we have a full description of the virus diseases followed by the bacterial diseases and infestations. There is a good account of the School Health Service.

This book belongs to all those interested in the advancement of Pædiatrics. The writing flows from the first to the last page and the author constantly stimulates us with his original thought.

**Spastics in Cheyne Walk. An Account of the Centre for Spastic Children, Cheyne Walk, Chelsea.** Edited and compiled by Joan Saunders and Marjorie Napier on behalf of the Friends of the Centre. (Pp. xiv+156; illustrated. 20s.) London: Pitman Medical Publishing Co. Ltd. 1957.

This is an excellent book and the purpose of it is defined in the foreword by Admiral Godfrey, Chairman of the Chelsea Group of Hospitals. This book has been written to provide those who contemplate forming a centre for Spastics with information regarding the layout of such a centre, and the type of staff required to run it. This centre deals with the pre-school child as the local authorities have the responsibility of dealing with physical and mental incapacity when the child reaches school age.

We will look forward in due course to a detailed report on the cases treated at this centre over a period of years, showing the degree of improvement that has been obtained in their mental and physical conditions according to their original clinical grouping.

Any body of people contemplating setting up a centre for the treatment of spastic paralysis should read this book.

## SYMPOSIUM ON RECENT DEVELOPMENTS IN IMMUNIZATION AGAINST BACTERIAL DISEASE

## The Basis of Immunity to Anthrax

By H. SMITH, D.Sc., Ph.D., B.Sc.

*Microbiological Research Establishment, Porton, Wilts*

IN this précis, various preparations which immunize animals against anthrax will be described, and their relationship to the factors which appear to determine the virulence of *Bacillus anthracis*, will be discussed.

### NON-TOXIC IMMUNOGENIC PREPARATIONS FROM *B. anthracis*

Pasteur first vaccinated against anthrax using living attenuated cultures, and to-day live uncapsulated strains of *B. anthracis* (e.g. the "Sterne" strain) are still used for vaccinating bovines. The immunogenic products of the growth of *B. anthracis, in vivo*, were first demonstrated by Bail and Weil (1911) in the œdema fluid from infected animals. Watson *et al.* (1947) showed the immunogenic activity of such fluid was associated with the $\beta$ and $\gamma$ globulins and Smith and Gallop (1956) isolated from it an immunogenic, high molecular weight lipoprotein containing carbohydrate residues.

Attempts to produce a dead immunogenic preparation *in vitro* did not succeed until some thirty to forty years after the work of Bail and Weil. Gladstone (1946) finally produced an immunogenic culture filtrate in a serum medium. Later, an immunizing antigen was obtained in a synthetic medium, first by Wright *et al.* (1954), and then in greater yield by Belton and Strange (1954); it appeared to be a protein (Strange and Belton, 1954).

The preparations described above would actively protect guinea-pigs, rabbits and monkeys against anthrax but only appeared to have low-grade effect in mice; preliminary information from a trial being conducted at present on personnel from the goat hair industries of U.S.A. indicates that the immunizing antigen produced *in vitro* in a synthetic medium is effective in protecting man against anthrax (Brachman and Wright, 1958). In contrast to the immunogenic anthrax toxin described below, these various preparations neither produced œdema when injected intradermally nor were lethal when injected intravenously.

### THE VIRULENCE FACTORS OF *B. anthracis*

The virulence of *B. anthracis* is determined by the presence of at least two factors—an extracellular toxin and capsular polyglutamic acid (for a complete series of references *see* Smith and Keppie, 1955; and Smith, 1958). The anthrax toxin was first recognized in the blood of guinea-pigs dying of anthrax but later was produced *in vitro;* it is lethal when injected intravenously and produces an extensive area of œdema when injected intradermally. The toxin enhances the virulence of an attenuated strain of *B. anthracis*, inhibits the phagocytosis of *B. anthracis* by guinea-pig polymorphs, and inhibits the action of an anthracidal substance present in some normal sera and in extracts of leucocytes; it therefore acts as an aggressin in the early stages of anthrax. The toxin is a powerful immunizing antigen.

Capsular polyglutamic acid has been isolated from organisms grown *in vivo*. Like the toxin, it is an aggressin but it is non-lethal and does not evoke œdema. Furthermore, neither isolated polyglutamic acid nor that present in dead capsulated organisms is immunogenic.

### THE RELATIONSHIP OF NON-TOXIC IMMUNOGENIC PREPARATIONS TO THE TOXIN

Since the immunogenic toxin is produced by *B. anthracis, in vivo*, it appears to be the prime basis for immunity to anthrax. There is, however, a very strong connexion between this toxin and the two important non-toxic immunogenic preparations just described—the lipoprotein isolated from œdema fluid and the "*in vitro* antigen", i.e. the purified preparation (Strange and Belton, 1954) from culture *in vitro*.

Table I shows that there is a strong serological connexion between these two preparations and the anthrax toxin, because the latter is neutralized by sera prepared against the former. To follow the connexion farther, an important property of the anthrax toxin must be described. The toxin consists of two components; one (factor I) is deposited quickly during ultracentrifugation leaving the second (factor II) in the supernatant (Smith *et al.*, 1956). The

TABLE I.—SPECIFIC NEUTRALIZATION OF THE TOXIN OF *B. Anthracis*

| Toxin injected after mixing with ½ vol. of: | Œdema in guinea-pig (0·2 ml. i/d) | Lethality in mice i/v 1 ml. | 0·5 ml. |
|---|---|---|---|
| Saline .. .. .. .. .. | +++ | 25/25 | 23/25 |
| Normal horse serum .. .. .. | +++ | 10/10 | 11/15 |
| Horse antiserum (to spore vaccine) .. | Nil | 0/15 | 0/15 |
| Horse antiserum (to "*in vitro* antigen") | Nil | 0/10 | 0/15 |
| Guinea-pig antiserum (to lipoprotein) .. | Nil | 0/5 | — |

two components act synergically in tests for œdema production and lethality (*see* Table II). Stanley and Smith (1958) and Sargeant and Smith (1958) have purified factors I and II using the cellulose ion exchange columns of Peterson and Sober (1956). The most purified sample of factor I is a lipoprotein containing carbohydrate residues, and purified factor II is largely protein. Both factors very easily lose their potential toxicity even at 0° C. but retain their antigenic character.

There is little doubt that the non-toxic lipoprotein formerly isolated from œdema fluid was factor I of the anthrax toxin which had lost its potential toxicity in the separation procedure; indeed, experiments on active factor I showed that such procedures did destroy its potential toxicity.

The "*in vitro* antigen" appears to contain components connected with both factors of the anthrax toxin. This is indicated by two lines of evidence. Firstly, the "*in vitro* antigen" (*a*) will replace factor II in the synergic mixtures with factor I for œdema production or mouse lethality tests and (*b*) will replace to some extent factor I in the synergic mixtures with factor II for mouse lethality tests (*see* Table II). Secondly, the "*in vitro* antigen" contains two com-

TABLE II.—SYNERGIC MIXTURES OF FACTOR I WITH FACTOR II OF THE ANTHRAX TOXIN AND WITH THE "*in vitro* ANTIGEN"

| Material | Œdema production i/d, guinea-pig 0·2 | 0·1 | 0·05 ml. | Mouse lethality i/v 2 | 1 | 0·5 | 0·25 ml. |
|---|---|---|---|---|---|---|---|
| Factor I* alone .. .. | +++ | ++ | + | — | 0/5 | 0/5 | 0/5 |
| Factor II* alone .. .. | + | Trace | Nil | 6/25 | 1/25 | 0/25 | — |
| "*In vitro* antigen"* alone .. | Nil | Nil | Nil | 1/10 | 0/10 | 0/10 | — |
| *Mixtures* | | | | | | | |
| Factor I .. .. .. + Factor II .. .. .. | 0·05 ml. + 0·1 ml. | | +++ | | 0·25 ml. + 0·5 ml. | | 5/5 |
| Factor I .. .. .. + "*In vitro* antigen" .. .. | 0·05 ml. + 0·1 ml. | | +++ | | 0·25 ml. + 0·5 ml. | | 5/5 |
| Factor II .. .. .. + "*In vitro* antigen" .. .. | 0·1 ml. + 0·1 ml. | | + | 0·5 + 0·5 | 1·0 ml. + 1·0 ml. | | 2/5, 8/10 |

*13 ml. of original toxin produced 1·5 ml. factor I and 7 ml. factor II. The "*in vitro* antigen" of our colleagues Strange and Belton (1954) was made up at 0·1% w/v. All œdema production and lethality were specifically neutralizable by anthrax antiserum.

ponents which form common serological precipitation lines with factors I and II of the anthrax toxin in the standard procedure on Ouchterlony plates using anthrax antiserum prepared against the "*in vitro* antigen" (*see* Fig. 1) or against live spores. The relevant components

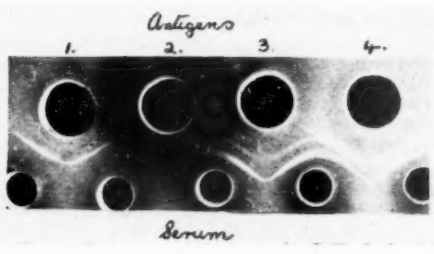

FIG. 1.—Serological precipitation lines on Ouchterlony plates. Antigen 1.—Purified factor I of anthrax toxin 0·3 mg. Antigen 2.—Crude anthrax toxin 8 mg. Antigen 3.—Purified factor II of anthrax toxin 2·6 mg. (this still contains approx. 2% of factor I). Antigen 4.—The "*in vitro* antigen" 0·3 mg. Serum.—anthrax antiserum prepared against the "*in vitro* antigen" (a similar picture is obtained using antiserum prepared against live spores). With different batches of toxin and different sera the line corresponding to factor I sometimes appears as a double line.

in the "*in vitro* antigen" are not exactly factors I and II of the anthrax toxin. Thus, apart from the obvious fact that the "*in vitro* antigen" is non-toxic, this antigen when it acts as factor II will only increase the œdema production of an amount of factor I which has a small inherent effect; it will not, as does authentic factor II, form an œdema-producing mixture with a smaller and separately unreactive amount of factor I. Furthermore, the "*in vitro* antigen" has no synergic effect on factor II as regards œdema production (*see* Table II).

## Summary

Of the two main virulence factors of *B. anthracis*—namely the toxin and capsular polyglutamic acid—the toxin is immunogenic and forms the prime basis for immunity to anthrax. The toxin consists of two factors which act synergically, and lose their toxicity very easily while retaining their antigenicity.

A non-toxic immunogenic vaccine prepared *in vitro*—an excellent practical vaccine—contains components which are closely connected with both factors of the anthrax toxin.

# Strain 19 and Other Brucella Vaccines

By E. C. Hulse, B.Sc., M.R.C.V.S.

*Ministry of Agriculture, Fisheries and Food, Central Veterinary Laboratory, Weybridge*

## Introduction

Prior to the introduction of S.19 vaccine to this country in 1941, a broth culture *Br. abortus* vaccine had been issued from Weybridge for many years. Under certain circumstances this vaccine was probably fairly efficient but its antigenic properties were unknown and it was rightly replaced by the S.19 vaccine.

Vaccination with S.19, an attenuated smooth strain (originally isolated by Cotton and Buck in 1923), had been started some years earlier in the United States and, by 1939, it had become firmly established there for the control of bovine brucellosis. The production of the liquid vaccine was begun at Weybridge with the assistance and advice of the United States Bureau of Animal Industry and output rapidly increased until an annual production of three-quarter million 5 ml. doses was attained. In 1944, the Ministry of Agriculture introduced the Calfhood Vaccination Scheme, whereby heifer calves from the age of 6 months to breeding age could be vaccinated at a small charge to the farmer by his own veterinary surgeon or by the staff of the Ministry. The scheme proved to be very successful and to-day over half of the vaccine issued is used for calfhood vaccination.

## Methods of Vaccine Preparation

In the preparation of the vaccine, care is taken to ensure that the smooth phase of the organism is always employed; the antigenicity of the vaccine is greatly reduced if dissociation is allowed to occur. For this reason the strain has always been cultivated on potato agar, although new techniques are now being evolved for production in a liquid medium; Roux flask culture is always laborious and the contamination risks are considerable. In 1956 the vaccine department at Weybridge moved into a new building equipped with the latest methods of ventilation for the production of a sterile atmosphere; the general improvements resulting from this have increased the yield by almost 20%.

Liquid culture techniques have been used by van Drimmelen (1956) at Onderstepoort for the production of S.19 vaccine. He has employed mechanical shaking of liquid cultures in large glass containers and, more recently (1957), the vortex system where 80 litres of liquid are revolved at 1,000 r.p.m. for seventy hours and a 2,000 to 6,000-fold increase in growth

obtained. At Weybridge plans are now well forward to introduce experimentally the continuous culture system employed at Porton. In this apparatus there is a periodic flow of fresh liquid medium into a container which is mechanically stirred and supplied with sterile air through a sparger; the vaccine concentrate is drawn off at intervals at the rate of about one litre per hour.

### Freeze-drying of S.19 Vaccine

Freeze-dried S.19 vaccine has been produced in recent years by commercial laboratories and others in several countries and in particular in the United States; the commercial undertakings have, quite understandably, not been prepared to divulge the medium used for the suspension of organisms prior to freeze-drying. Skimmed milk is most frequently used as the suspending medium but at Weybridge the re-suspending properties of this medium have not been satisfactory and the medium of Naylor and Smith (1946) (basically thiourea, dextrin and ascorbic acid) has been used instead. This medium has produced a satisfactory product which reconstitutes instantaneously; after freeze-drying the resultant viability is over 70% of the original count and the residual moisture is about 1%.

To facilitate handling of the vaccine in the field, freeze-drying in glass-sealed ampoules has been avoided and rubber-stoppered bottles have been employed. A butyl rubber mix has been found which appears to be relatively impenetrable under vacuum to water vapour. The vaccine is dried with the rubber stopper *in situ* in the mouth of the bottle and a special two-pronged stopper has been developed for this purpose; the stopper is pushed home under vacuum when the drying cycle is completed.

The recommended concentration of viable organisms in S.19 vaccine at issue is $60 \times 10^9$ and the minimal vaccinating dose is $25 \times 10^9$; at Weybridge it has been considered advisable to employ a greater concentration than this and the corresponding figures are $80 \times 10^9$ and $40 \times 10^9$ respectively.

The object of freeze-drying S.19 vaccine is to retain its viability for as long as possible after drying. The "life" of the liquid vaccine is three months at 4° C. and, to be of any practical value, the duration of viability of the freeze-dried vaccine must be greatly in excess of this. It has been shown that dried vaccine will retain an issue viable count for nearly two years in the cold store and there seems to be no reason why this period should not be considerably extended. Tests on the viability of the vaccine at room temperature have been carried out after storage in the cold store for twelve months and a satisfactory count has been obtained up to the fourth week at room temperature. Counts on the vaccine stored at room temperature immediately after freeze-drying have indicated that a vaccinating dose can still be obtained up to the twelfth week compared with a maximum of four weeks in the liquid vaccine held under similar conditions.

Tests are now being performed on the dried vaccine under transportation conditions. Samples of vaccine have been distributed to various offices of the Ministry in Scotland and the West of England and have been returned at regular intervals for testing. Vaccine stored in the cold in these offices has retained a vaccinating dose for six months, which is the present extent to which the tests have been applied. Similar tests on an extended scale are now in hand and the vaccine is submitted to conditions similar to those to which it would be subjected in veterinary practice; the examination of returned samples has given encouraging results.

In a limited field trial a small number of calves and adult cows were vaccinated with the freeze-dried vaccine suspended in Smith-Naylor medium; no abnormal reactions were observed. The agglutinin response, ranging in titre from 1/40 to 1/320, followed the normal pattern of the liquid vaccine and the local reactions at the inoculation sites were not noticeably more severe. The temporary drop in milk yield which generally accompanies the use of liquid vaccine was also similar.

To allow for the average 30% loss of viability of the vaccine during the freeze-drying process, more vaccine concentrate is required and the various liquid culture processes already referred to may be of value in mass production techniques. Consideration will have to be given to the problem of the removal of the spent culture from the bacterial mass prior to freeze-drying and its replacement with the suspending medium. Greater contamination risks in handling of the mass culture will be involved and there may be the added risk of loss in viability because it will not be possible to freeze the bacterial suspension so rapidly after harvesting and prior to freeze-drying.

### Application of the Vaccine in the Field

McDiarmid (1957) has reported the results of a large experiment at Compton involving approximately 500 cattle and extending over seven years. Young cattle were vaccinated in groups: once at 6 months; once at 18 months; twice at 6 and 12 months; and three times at 6, 12 and 18 months. Cattle from each of these groups and controls were challenged with virulent *Br. abortus*, some at the 1st pregnancy, some at the 2nd and so on up to and including

the 5th pregnancy. The immunity did not apparently diminish over the five pregnancies, irrespective of the method of vaccination employed. The triple vaccination gave a slightly better immunity than the single injection. Since, however, S.19 vaccine stimulates the production of agglutinins which cannot be distinguished from those resulting from natural infection, the single injection at 6 months of age is more desirable because the majority of animals vaccinated at that age return to the negative status by 18 months of age. The presence of agglutinins in the adult animal is disadvantageous for those who breed pedigree stock for sale or where it is desired to remove infected animals from a herd by blood testing. The use of a non-agglutinogenic vaccine is under investigation and this will presently be described.

The results of the Compton experiments show that one dose of S.19 vaccine at about 6 months of age will confer a satisfactory immunity against *Br. abortus* infection for at least five pregnancies.

## Adjuvant Vaccines

(*a*) *Br. abortus*.—In the early days of S.19 production a non-agglutinogenic strain produced by McEwen and known as 45/20 was also used, particularly in adult cattle. Unfortunately it was found to undergo mutation and its use was discontinued. Interest has been reawakened in this strain recently since McEwen and Samuel (1955) showed that a heat-killed adjuvant vaccine prepared from this strain successfully immunized guinea-pigs. McDiarmid and Sutherland (1957) have subsequently compared the efficacy in guinea-pigs of living, heat-killed and dead adjuvant vaccines prepared from strains 19 and 45/20. Vaccine prepared with S.45/20 by any of these methods produced no agglutinins. Dead organisms of both strains suspended in Ringer gave poor protection; S.19 vaccine, both living in Ringer and dead in adjuvant, produced a slightly better protection rate than strain 45/20. The 45/20 adjuvant vaccine was slightly more effective than that prepared from the living suspension in Ringer.

The results of this trial have encouraged the Compton workers to begin an extended experiment on similar lines in cattle of breeding age. McDiarmid is of the opinion that the 45/20 adjuvant vaccine might be used as an adjunct to the present method of vaccination against brucellosis in cattle. It is suggested that, if the use of S.19 vaccine were eventually limited to calves of 6 months of age, the non-agglutinogenic S.45/20 vaccine could well be used in those herds where it was thought advantageous to vaccinate older animals also.

(*b*) *Br. melitensis*.—A somewhat similar situation now obtains with regard to the vaccination of goats against *Br. melitensis*. Renoux and his co-workers (1957) in Tunis have experimented with attenuated and adjuvant vaccines and the latest results show that a formol-killed vaccine prepared from a virulent strain of *Br. melitensis* suspended in a non-absorbable adjuvant gives a satisfactory immunity in goats for about six months.

Elberg and Faunce (1957) have shown that good protection can be obtained in pregnant goats by the use of a living strain of *Br. melitensis* which is smooth and avirulent; this is derived from a non-dependent mutant isolated from a streptomycin-dependent population. Its disadvantage is that, like S.19, it stimulates the production of agglutinins.

Jones, Thomson and Alton (1958) at Weybridge have shown that an adjuvant vaccine derived from a killed rough culture of *Br. melitensis* produces the same immunity in guinea-pigs without producing agglutinins as a similar vaccine prepared from a smooth agglutinogenic strain. This work has now been carried a step farther by comparing the value of rough and smooth adjuvant vaccines in goats with the living smooth vaccine obtained from Elberg. The results have shown that there is not a significant difference between the three vaccines when challenged with graded doses of virulent *Br. melitensis*. The living vaccine of Elberg was most effective, however, in preventing a generalized infection with the larger doses of the virulent strain. Although this vaccine is agglutinogenic, it is anticipated that it will produce better immunity under field conditions than either of the dead vaccines. There is, therefore, a striking similarity between this vaccine and S.19 *abortus* vaccine in this respect.

## Conclusion

To summarize, the campaign to control and eliminate bovine contagious abortion by the use of S.19 vaccine in Great Britain has given and continues to give satisfactory results. Approximately half a million heifer calves are vaccinated annually under the Calfhood Scheme and this single injection gives, in well over 90% of cases, a satisfactory protection against infection for at least five pregnancies. The keeping qualities of the vaccine can be enhanced considerably by freeze-drying and it is anticipated that the vaccine will be issued as a freeze-dried product from Weybridge in the next few months. Work on mass liquid culture methods merits further investigation but vaccine derived from such a source might have to be subjected to a trial in cattle before one could be assured that it is entirely satisfactory as an immunizing agent.

Preliminary experiments on an adjuvant vaccine derived from the non-agglutinogenic strain 45/20 show considerable promise. The combination of these two vaccines with the

intensification of the use of S.19 vaccine in young animals should enable all stock to become immunized and such a procedure would go a long way to freeing this country completely from a disease which has occasioned such heavy losses in the past. Finally, the very serious problem in some other countries of *Br. melitensis* infection in goats and its transmission to man may eventually be resolved by the use of a vaccine on similar lines to the S.19 vaccination against *Br. abortus* infection in cattle.

## Immunological Response to Freeze-dried BCG

By J. UNGAR, M.D.

*Glaxo Laboratories Ltd., Greenford*

VACCINATION with BCG has become established in many countries as an effective measure for the control of tuberculosis. There have been marked differences of opinion in this country as to the value of BCG vaccine, but the recent report of the Medical Research Council (1956) on vaccination of school leavers has shown it to have proved of value under certain conditions. A liquid vaccine was used in this trial—up to now the universally accepted form of BCG administration, except in Japan.

It has been realized that the liquid vaccine has certain disadvantages. First, the culture has to be closely watched for changes in antigenicity and virulence due to the continuous subculturing at ten- to fourteen-day intervals, and elaborate tests are necessary for this purpose. More important for the practical use of the vaccine are two other handicaps: it has only a limited life of about fourteen days and there is no direct evidence as to the antigenicity and safety of the vaccine when it is used. The vaccine consists of live bacteria and contains no antiseptics, so that slowly-growing contaminants would be difficult to detect by conventional sterility tests. The biological control of BCG is a long process. Apart from the safety tests, which include those for absence of virulence in the BCG, it is important to establish that the particular batch contains the required number of viable organisms. A much higher content is liable to produce untoward local reactions (ulcers, lymphadenitis); a low content may result in an unsatisfactory tuberculin conversion rate. Such variations in effect between batches of liquid vaccine have been noted.

It has been known that bacteria can be freeze-dried without affecting their biological characteristics, and it was obviously sensible to try to apply this technique to BCG, particularly in view of the considerable advances made in freeze-drying techniques as used in the preparation of antibiotics.

An effective freeze-dried BCG vaccine should have the following advantages over the liquid type: (*a*) *Stability*.—The vaccine would under suitable conditions be stable for at least one year and be available for use at any time during that period. (*b*) *Uniformity*.—The vaccine could be standardized in terms of viable bacteria, so avoiding undesirable variations between batches. (*c*) *Safety and potency*.—Each batch can be submitted to safety tests and to potency tests to establish its antigenicity before release.

### GLAXO FREEZE-DRIED BCG VACCINE

A freeze-dried vaccine should be prepared in such a manner that it reconstitutes on addition of fluid to a homogeneous suspension of cells with a minimum of clumping. The medium in which the bacteria are dried should be non-antigenic and not liable to cause any reaction. In the past vaccines have been prepared in serum, 50% glucose, 1% sucrose, various concentrations of lactose, &c., but most of these have disadvantages. After prolonged trials we have chosen as a suspending agent an aqueous solution of 8·3% of dextran with 7·5% glucose. The vaccine (Ungar *et al.*, 1956) is prepared from the same strain of BCG as that used in the M.R.C. trial; in our experience there is no essential difference in the strains of BCG used in various laboratories and freeze-dried vaccine can be prepared from any of them.

The strain is grown in a submerged culture in Sauton's medium, with addition of 1/4,000 w/v Triton "WR 1339", at a temperature of 37° C. for nine days. The growth is centrifuged and the deposit reconstituted in the dextran-glucose medium and standardized to a final con-

centration by opacity measurements in the Spekker photometer. The vaccine is filled into special moulded ampoules, then freeze-dried and sealed *in vacuo*. After preparation it is tested for its content of viable cells and on laboratory animals for safety and potency. These tests take about ten weeks: only after their conclusion are batches released for general distribution. The freeze-dried material is easily reconstituted for intradermal use by adding 1 ml. of either sterile water or physiological saline to the ampoule.

The viability count of the reconstituted freeze-dried vaccine is worth mentioning, because it is this property of the vaccine that it is particularly important to standardize. During the process of freeze-drying, depending on conditions, a proportion of the suspension survives; in our technique it is about one-tenth of the bacteria originally present. We found that a modification of O'Hea's method (1955) was the most suitable for our purpose; in this 0·02 ml. drops from a platinum dropping pipette are applied to the surface of the medium held in small bottles (7 ml. bijou bottles) filled with 10% blood agar medium. The vaccine is diluted in Sauton's medium, with 1/4,000 Triton added to inhibit aggregation, and tenfold dilutions from $10^{-3}$ to $10^{-6}$ are made in duplicate from each batch. The diluted solutions are incubated in six bottles of medium, and an average of twelve counts is taken. The method, as used in our laboratory, seems to give reproducible results, and we believe that it enables us to issue vaccines of a constant potency and with satisfactory keeping properties for at least twelve months when stored below 20° C.

## Biological Studies in Animals

One of the basic properties of the BCG vaccine is induction of tuberculin-sensitivity in the inoculated animal. The generally accepted view being that tuberculin allergy is a convenient index of acquired resistance, we have used the tuberculin conversion test to assess the quality of the vaccine. It has occasionally been stated that the freeze-dried vaccine is slower in inducing tuberculin allergy than is a freshly prepared fluid vaccine. We have found that the time of the appearance of the reaction to tuberculin, and the intensity of the reaction, depend on the number of viable organisms in the vaccinating dose (Table I). Similarly, the size of the

Table I.—Tuberculin Conversion in Guinea-pigs after Immunization with Vaccines of Different Viability

| Vaccine Batch No. | Viable cell count (per ml.) | Tuberculin test (time after vaccination) | Tuberculin reaction (mm. induration) twenty-four hours after 10 units PPD intradermally (average of six animals and range) |
|---|---|---|---|
| Freeze-dried 94b .. | $20{\cdot}8 \times 10^6$ | 20 days | 8·7 ( 7–12) |
| | | 28 days | 15·7 (14–18) |
| Freeze-dried 73 .. | $10{\cdot}0 \times 10^6$ | 20 days | 8·3 ( 6–11) |
| | | 28 days | 15·5 (14–16) |
| Freeze-dried 62 .. | $0{\cdot}7 \times 10^6$ | 20 days | 8·3 ( 6–10) |
| | | 28 days | 11·2 ( 7–13) |
| Freeze-dried 50 .. | $0{\cdot}1 \times 10^6$ | 20 days | 2·2 (0–7) |
| | | 28 days | 8·2 (7–11) |

| | | 28 days | 0 (0) |
| Danish liquid vaccine (1·97) | $26 \times 10^6$ | 20 days | 6·2 (0–9) |
| | | 28 days | 11·0 (9–13) |

Vaccination dose and route: 0·1 ml. injected intradermally. 0 indicates less than 2 mm.

Table II.—Relation Between Viable Cell Count of Vaccines and Size of Local Reaction at the Vaccination Site

| Batch No. | Viable-cell count | Extent of local lesion at vaccination site at 17 days after vaccination: G.-pig 1 | G.-pig 2 | G.-pig 3 | G.-pig 4 | G.-pig 5 | G.-pig 6 |
|---|---|---|---|---|---|---|---|
| 78 | $60{\cdot}0 \times 10^6$ | 4 | 4 | 4 | 3 | 4 | 3 |
| 94b | $20{\cdot}8 \times 10^6$ | 4 | 3 | 2 | 2 | 3 | 2 |
| 73 | $10{\cdot}0 \times 10^6$ | 2 | 2 | 3 | 2 | 2 | 2 |
| 62 | $0{\cdot}7 \times 10^6$ | 2 | 2 | 2 | 2 | 2 | 1 |
| 50 | $0{\cdot}1 \times 10^6$ | 0 | 0 | 1 | 1 | 1 | 1 |
| 50x | 0 Heat killed | 0 | 0 | 0 | 0 | 0 | 0 |

0 = No lesion. 1 = Small < 4 mm. lesion with small scab. 2 = Lesion 4–6 mm. diameter with firm 2–3 mm. scab. 3 = Lesion 7–10 mm. diameter with firm 5–6 mm. scab and some ulceration. 4 = Lesion > 10 mm. diameter with firm > 6 mm. scab, ulceration and deep necrosis.

vaccination papule after inoculating 0·1 ml. of the vaccine intracutaneously depends on the number of viable bacteria. Table II shows that the size of the local lesion was related to the viable cell content. By standardizing our vaccine to a required strength, we are able to issue biologically active vaccines and at the same time to avoid the danger of excessive local or regional (lymphadenitis) reactions, such as have occasionally occurred with liquid vaccines.

Protection tests in animals vaccinated with BCG are still in the experimental stage. No satisfactory answer can as yet be given from experiments on vaccinated guinea-pigs or mice subsequently challenged with virulent tubercle bacilli. An indirect method of assessing acquired resistance by measuring the radio-activity of disintegrated labelled mycobacteria in vaccinated and controlled animals is under investigation. This procedure might lead to a method for quantitative evaluation of the vaccine's efficacy.

## Biological Studies in Children

When we began our investigations we had no information on certain essential questions. They were:

(*a*) What should be the content of viable organisms in the vaccine to give a satisfactory tuberculin conversion without untoward reactions?

(*b*) Does the biological effect of the vaccine diminish with the time of its storage even though the viable count does not alter?

(*c*) Should the dose for babies be different from that for older children or adults?

(*d*) Is the vaccine suitable for different routes of administration?

It is a great pleasure to state that, thanks to the support and unceasing efforts of Professor W. Gaisford, Dr. M. Griffiths, Dr. J. Lorber, Dr. W. Hartston, Professor F. Heaf, and more recently of the M.R.C. Committee on Tuberculosis and particularly Drs. D. G. Evans and T. Osborne, we have been able to formulate the correct composition of the freeze-dried vaccine as an effective and safe antigen for intracutaneous vaccination.

Lorber and his team (1956), and Griffiths and Gaisford (1956) in their independent trials, have established that the freeze-dried vaccine is an effective antigen for young babies, as is the fluid Danish vaccine. They have also confirmed the considerable practical advantages of the dried over the liquid vaccine for use in clinics.

(*a*) The dried vaccine enabled us to answer the first basic question: what should be the content of the ampoule, how much should be injected into a baby to achieve the object? In the preliminary trials on 276 newborn babies, Lorber *et al.* (1956) had found that vaccines of low viability produce smaller lesions, less involvement of axillary lymph nodes and a slightly lower conversion (94%) than the liquid Danish vaccine. Shortly afterwards Griffiths and Gaisford (1956) reported their results with freeze-dried batches of different viabilities. They concluded that a satisfactory tuberculin conversion occurred after intradermal inoculation of 0·1 ml. of the vaccine, provided enough viable organisms were present. "With such a vaccine the rate and extent of development of allergy, the size of the local reaction and the response to tuberculin testing a year after vaccination were all comparable with the results produced by injection of 0·037 mg. of the Danish fresh vaccine."

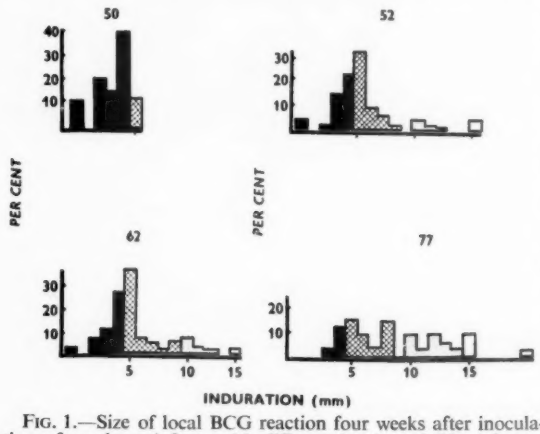

FIG. 1.—Size of local BCG reaction four weeks after inoculation of newborn infants with different batches of Glaxo freeze-dried BCG vaccine.

Fig. 1 shows that the size of the local lesion is directly related to the viable cell content of the vaccine used.

Batch 50 had a viable cell count of $0{\cdot}1 \times 10^6$ org./ml.
Batch 52 " " " " " " } $1{\cdot}2 \times 10^6$ org./ml.
Batch 62 " " " " " "
Batch 77 " " " " " " $10{\cdot}0 \times 10^6$ org./ml.

Fig. 2 shows the degree of Mantoux sensitivity to 100 TU four weeks after vaccination of newborn infants, and also demonstrates that the time of appearance of the allergy is proportional to the viable count.

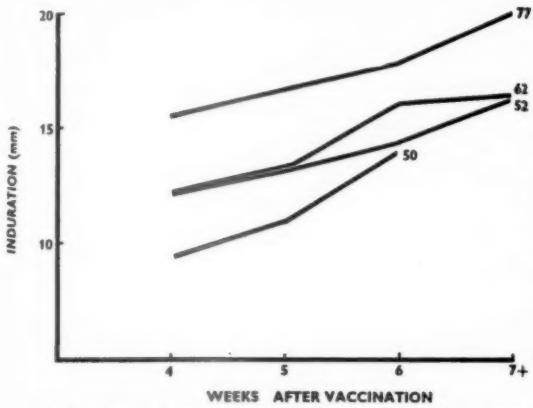

FIG. 2.—Rate of development of Mantoux sensitivity to 100 TU in newborn infants after injection of different batches of Glaxo freeze-dried BCG vaccine.

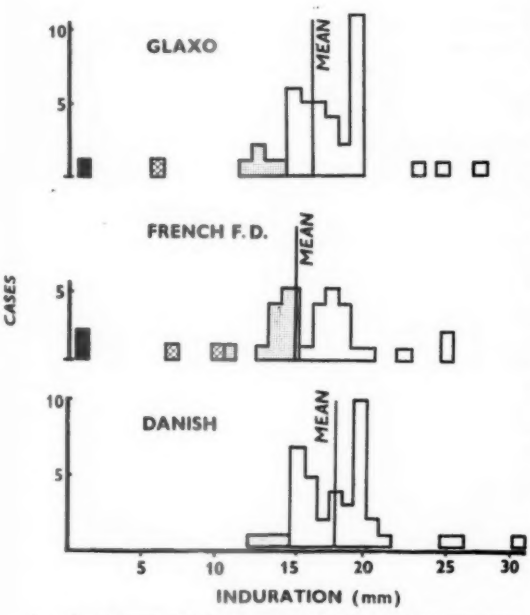

FIG. 3.—Degree of Mantoux sensitivity to 10 TU one year after vaccination of newborn infants with fresh Danish (0·075 mg.), Glaxo freeze-dried (Batches 52 and 62) and French freeze-dried vaccines.

Figs. 1, 2 and 3 are reproduced from Griffiths and Gaisford (1956) by kind permission of the Editor of the *British Medical Journal*.

The relationship between viable counts, size of local reaction to the inoculum and degree of Mantoux sensitivity is thus established. On subsequent trials it has been found that batches having viability counts equal to that of Batch 50 or lower, containing approximately 10,000–30,000 viable bacilli per inoculating dose, are unsatisfactory. On the other hand, batches of high viability, such as 77, containing 1 million organisms/dose, are more potent than the Danish liquid vaccine, but they tend to produce large lesions at the site of inoculation and regional lymphadenitis in a high proportion of babies. According to Griffiths and Gaisford, vaccines containing about 2–3 $\times$ $10^6$ viable cells are optimal; they produce nodules of fairly uniform size with little or no complication and a satisfactory lasting tuberculin conversion rate.

Similar conclusions to those of Griffiths and Gaisford were drawn by Lorber and coworkers (1957); Table III summarizes their results. When tested for tuberculin allergy with 10 TU four weeks after vaccination, babies inoculated with Batch 77 showed the highest conversion rate (86·8%).

The available results indicate that the tuberculin conversion after the freeze-dried vaccine is satisfactory. Fig. 3 compares the response to 10 TU tuberculin one year after vaccination with either the freeze-dried vaccine or liquid Danish vaccine. Lorber (1957) has retested 50 school children vaccinated a year previously with Batch 93a and found that all were tuberculin positive (jelly test or Heaf test).

It seems likely that tuberculin sensitivity produced by the dried vaccine will persist as long as that from the Danish vaccine, assuming that the size of the primary lesions reflects the extent of biological response to the antigen.

TABLE III.—VACCINATION LESIONS IN INFANTS AFTER BCG VACCINATIONS WITH BATCHES OF DIFFERING VIABILITIES

| Details | Batch of vaccine used | | | |
|---|---|---|---|---|
| | Freeze-dried Batch 50 | Freeze-dried Batch 77 | Freeze-dried Batch 93a | Danish liquid vaccine |
| Viable count .. .. | $0{\cdot}14 \times 10^6$/ml. | $23{\cdot}0 \times 10^6$/ml. | $11{\cdot}0 \times 10^6$/ml. | $5{\cdot}02 \times 10^6$/ml. |
| Number seen .. .. | 102 | 123 | 158 | 173 |
| Diameter of papules (mm.) Range | 1–15 | 2–28 | 2–28 | 3–18 |
| Diameter of papules (mm.) Average | 6·1 | 12·5 | 10·3 | 9·3 |
| Number of infants with papules of 20 mm. or more | 0 | 8 | 1 | 0 |
| Number of infants with papules of 15–19 mm. .. | 1 | 30 | 1 | 0 |
| % of infants with papules of 15 mm. or more .. .. | 0·9 | 30·9 | 15·8 | 6·3 |
| Number of infants with axillary lymph glands 5 mm. or more .. .. .. | 0 | 13 | 4 | 7 |

(From Lorber *et al.*, 1957.)

(*b*) In Lorber's series, vaccines were five to ten months old when vaccinations were begun. There was no evidence of deterioration, as judged either by the size of local reaction or by the extent of tuberculin response, in babies vaccinated with vaccines stored at room temperature throughout the four months' trial. Groups of infants vaccinated with it either at the beginning or at the end of the trial period gave the same response.

(*c*) The dried vaccine was standardized at the early stages with the primary object of using it for vaccinating babies. The first intimation that the same product might be suitable also for vaccinating school leavers came from Dr. W. Hartston, Tuberculosis Officer of the London County Council. In his preliminary trials Dr. Hartston compared Batch 62 with the Danish liquid vaccine and found that the responses after intradermal inoculation of either were similar. Since then, use of the freeze-dried vaccine has been extended to school leavers and reports from Dr. Hartston, Professor Heaf, Dr. Lorber and Dr. Griffiths and others have established that the original vaccine is also suitable for immunizing school leavers and contact cases in adults. This finding indicates that a single type of vaccine can be issued for general use.

(*d*) The intracutaneous vaccine is not the only type that has been available. My colleagues, Dr. P. W. Muggleton and Miss J. P. Farmer, have modified the freeze-dried technique to enable them to produce alternative types of freeze-dried vaccines suitable for oral use or for percutaneous administration by the multiple puncture method. The latter has been studied by Professor Heaf and by Dr. Hartston, whose experience seems to indicate that the multiple puncture method will give a satisfactory tuberculin conversion rate without causing any of the marked local lesions sometimes seen after intracutaneous inoculations.

There are many aspects of BCG vaccination still open to discussion and I can only briefly mention them. One is the question of the optimal age for vaccination. Pædiatricians would like to have vaccination begun before puberty. Occasionally doubts are expressed about the safety of the vaccine, but the reports of WHO on BCG mass imunization should convince any unbiased reader of its innocuousness. The opinion has recently been expressed that BCG has lost its value in communities with a high standard of living, because of the continuous decline of the tuberculosis mortality rate. This argument seems, however, to ignore the fact that the morbidity from the disease and the number of new cases of tuberculosis is still surprisingly high (report of the Medical Advisory Committee of the Research Foundation, 1957). It has to be admitted that the wider use of vaccination involves a reduction in the diagnostic value of the tuberculin test. Clinicians and epidemiologists will have to decide whether or not the extent of the protection afforded against tuberculosis makes this sacrifice worth while.

## Preventive and Curative Medicine in Ancient Peru [*Abridged*]

### PRESIDENT'S ADDRESS

By Sir WELDON DALRYMPLE-CHAMPNEYS, Bt., C.B., M.A., D.M., F.R.C.P.

#### INTRODUCTION

IN choosing Preventive and Curative Medicine in Ancient Peru for my Presidential Address I have hoped to communicate to my readers some of the fascination that this subject has had for me, even before I went to that country. A great deal of work has been done to elucidate the ancient cultures of South America, including Peru, since Prescott's great book appeared just a hundred years ago, and the more that is found the more interesting and intriguing does the scene appear. The aspect of these civilizations to which I shall refer is not the least remarkable of their manifestations, and though the curative side of the picture can be more or less matched in other cultures, the preventive side, I venture to assert, was in many ways in advance not only of other contemporary civilizations, but of all throughout the world up to the end of the nineteenth century.

*The sources of our information.*—It is a well-known but very remarkable fact that the Indians of ancient Peru had no written language, though they had traditions handed down, in a carefully edited form, by minstrels, also a crude method of recording statistics, and possibly certain simple facts, by means of the *quipu* (which I will explain later); and finally, from the beginning of the fifteenth century, under the Inca Emperor Pachacutec, a series of paintings recording historical events—paintings which did not, unfortunately, survive the Spanish conquest. Consequently the sources of information available are limited to mummies (some, 2,000 years old), ceramics, embroideries, weapons, &c., found in the tombs and cemeteries and wonderfully preserved by the dryness of the climate; the accounts of the Spanish conquistadores, which must be accepted with caution owing to their strong prejudices against "heathen" practices and the reticence or even deliberate deception of the conquered peoples; and finally the contemporary customs and languages of the Indian tribes.

*The peoples.*—The origin of the peoples of South America is unknown, though Baudin [5] points out that "the excavations of Junius Bird . . . in Southern Patagonia have shown that man was hunting sloth, horse, and guanaco in that region between 6000 and 7000 B.C., so he must have been in Peru before that". The Incas were one of the many tribes inhabiting ancient Peru, and belonged to a group of tribes living in the neighbourhood of Cuzco and speaking the *Quechua* language.

The Inca empire lasted from about A.D. 1000 to the Spanish Conquest.

*Preventive medicine and public health.*—The Inca state was one of the most benevolent despotisms the world has ever seen, and certainly one of the most efficient. The State saw to it that every subject, whatever his age, ability or health, had sufficient housing, nourishment, clothing, and amusement (according to Tschudi [9] there were 158 fiestas during the year), security in marriage, freedom of worship, protection from special industrial hazards, freedom from debt (there was no money), security from oppression (the Inca sovereigns never abused their power or allowed others to do so), and protection from enemies outside. All these benefits were theirs, provided that they were never idle during working periods, stayed in their own provinces except when going up to the capital, Cuzco, for a feast, and did not break the laws. The Incas, in fact, gave their subjects a moral code far in advance of the peoples surrounding them, for as Baudin [5] remarks, "the chiefs of most of the surrounding tribes were bloodthirsty tyrants and gave a bad example. On the coast there was

sodomy; in the eastern woods and on the meseta itself cannibalism prevailed". Garcilaso [6], the historian of the conquest whose mother was an Inca princess, describes how a tribe, the Caranquis, rebelled against the Inca because they were not allowed to eat human flesh, killed the Peruvians and devoured them.

In the Inca state the most elaborate and accurate statistics were kept of births, marriages, and numbers of the population of different ages; in addition to statistics relating to crops, stores of grain, arms, &c. The instrument used to record such statistics was the famous *quipu* (or *quipo*), a cord from which hung numerous knotted strings of different colours, the position of the knots indicating units, tens, hundreds and thousands. Men were specially trained to make the quipus and to interpret them and they are believed to have recorded not merely statistics, but even historical events.

A census of the whole population of the empire was carried out every year, the population being divided into age groups. The accuracy of these statistics was safeguarded by severe sanctions, for the keeper of the records (called the *quipu-camayu*) who did not know what he should know, or who lied, was punished with death, "without hope of reprieve" [8] and the Indian who ran away to escape the census was poisoned. Special envoys of the Inca called the people together for numbering, even when they were in *articulo mortis*.

Though labour was compulsory, the sovereigns took care that it did not exceed the power of the individual, and for this purpose account was taken of age, sex, health and the nature of the work in question. Never were governors more careful of the health of their people; the mining of mercury, which gives rise to "tremors and nervous spasms", was forbidden (Garcilaso lib. 8); fishing for pearls was also prohibited; only a small number of Indians were sent to the coca plantations, situated in hot and unhealthy country, and these workers were invariably inhabitants of hot districts (the Spaniards by neglecting this precaution wiped out whole tribes [10]). For very laborious tasks there was a rota system, according to a law which Garcilaso (lib.5) calls the law of "alternative labour".

## Curative Medicine

*Anthropology*.—Now what did the peoples of ancient Peru look like? We can form a good idea from mummies, figures on ceramics, and the appearance of present-day people of pure Indian blood.

"The Incas were rather short and stocky, averaging about 5 ft. 3 in. in height, with broad shoulders, and the deep chest associated with a people who live in the rarefied atmosphere of the high Andes. They had a brown skin, straight hair, rather a broad face with a prominent nose, straight or slightly hooked, and little facial hair [11]." They were a muscular people. The modern Peruvian Indian, living at high altitudes, probably closely resembles the Incas. His blood picture reveals a tendency to macrocytosis with a moderate increase of the corpuscular volume and of the hæmoglobin content of the corpuscles, an increased proportion of reticulocytes and an increased activity of the hæmopoietic organs. Blood group O is predominant and Snyder and Coca-Deibert have suggested that the South American Indians are a pure race which separated from the main human trunk before factors A and B appeared.

*Sexual life*.—The principal goddess of fertility was called Imaimana, but it was Viracocha, the Creator, who had ordained that man should multiply and abound.

The phallic cult was preponderant and is well represented in ceramics. There were also idols, such as Isphana, who were prayed to as protectors of the urinary passages.

The onset of menstruation in girls was celebrated by a feast called *quicuchicu*, and during the first menstruation the initiates ate nothing but crude maize for the first two days. On the fourth day they cleansed themselves and put on a dress called the *angallo axo* and white woollen sandals.

The Peruvians, especially the upper classes, had a horror of incest and marriage was prohibited between a man and his daughter, sister, aunt or niece, the Inca himself being the only exception, for he always married his sister.

The local governors were presented with wives by the Inca from among the Virgins of the Sun.

Sexual perversions were common among some of the tribes (but not the Incas) including sodomy, bestiality and exhibitionism, sometimes practised in the temples of gods to whom these practices were supposed to be pleasing.

Garcilaso relates that when an Indian general, Auqui Titu, conquered some coastal valleys in which he found sodomy being practised, the Emperor commanded that not only the actual offenders but also all initiates should be burnt alive in the public square, and that the trees on their land should be burnt down and the roots torn up, so that no memory of them should survive.

In the Inca state adultery and fornication were punishable with death.

*Artificial deformations.*—The practice of producing artificial deformities of different parts of the body seems to have prevailed in Peru from time immemorial and such deformations are well represented in ceramics.

The perforation of the nasal septum for the insertion of a *nariguera*, or disc with a ring top for attachment, was a common practice among the ruling caste. The name *paychi* seems to have been attached indifferently to this operation and to the corresponding perforation of the ears for the insertion of discs of increasing size. Though the wearing of both kinds of discs was a sign of caste, the perforation of the ear lobes had a special significance, and was, perhaps, a blood-rite, analogous to Jewish circumcision [12]. *Chicha*, an alcoholic beverage made from maize was used as an anæsthetic for this operation [13].

Deformation of the skull was also a common practice, the object and mechanism of which are still much debated. Lastres [11] describes two main types of deformation, the first, shown by skulls exhumed in the region of Tiahuanaco and around Lake Titicaca, he calls "la deformación echada", or flattened deformation, in which the frontal bone is flattened almost horizontally, forming a plane with the parietals and resulting in an antero-posterior elongation. The second type described by Lastres is called by him "levantada" or elevated, and is found in the coastal regions, especially in the tombs at Ancón. In this deformity the frontal bone is pushed upwards, as are also the parietals, by antero-posterior compression by means of a clamp-like apparatus called a *chuco*. Several other varieties of cranial deformation are also encountered. The object of this practice has been variously given as æsthetic, for the subjugation of conquered peoples, as a religious rite like circumcision, as a caste distinction, to frighten enemies, &c., but nothing is certain here. The *chuco* was apparently applied soon after birth and continued until the child was about three years of age, after which the skull grew in the required shape without further persuasion.

*The doctors.*—As with all primitive peoples the medical conceptions of the ancient Peruvians were based on their religious beliefs and their main object in life was to conciliate the supernatural forces surrounding them, asking some to spare them, others to aid them [1]. The perpetual state of fear in which they lived was, in fact, at times responsible for pathological changes. Every illness was, in their conception, the result of some fault committed either by the patient himself or his neighbours and the best way to discover the cause of the malady was to make a sort of confession to the priest-doctor, whose job it was to elucidate what had gone wrong.

It was, then, by means of magic that the cause of the malady was discovered and the means for its cure selected.

The persons who treated the sick were a combination of priest, magician and doctor, and were attached to some *huaca*, i.e. a place held sacred, either because of some important event which had occurred there, or because it was dear to some divinity, or was a place of burial. These priest-magician-doctors, known as *hampi-camayoc* (the Spaniards called them *brujos* or *hechiceros*, i.e. sorcerers) were very numerous. Fig. 1 shows one of them driving

FIG. 1.—Magic cure (after Tello). [Copyright.]

out the demon of a disease. Their functions were to offer sacrifices and offerings, to hear confessions, to give advice, and to heal by driving out the demon causing the disease, and finally to avert plagues and pestilences. Many people regard them as akin to *shamans*. These men or women were chosen in the first place from among those who were regarded as

set apart, e.g. those who had been born in the fields in a thunderstorm (called *chuqui-illa*), o those who were said to have been "born of the lightning", or "sons of the lightning", o twins or triplets. Other priests, known as *ccamascas* or *mascas* [2, 3], attributed thei powers to the thunder, the idea being that thunder had occurred close to them producing an internal commotion during which they were endued with power to heal with remedies o to answer questions put to them.

The persons who aspired to be priests or magicians went through a rigorous novitiate with fasting, bleeding, and a vegetarian diet consisting of herbs and maize. It was only after many months of painful abstinence that they were declared priests. During his novitiate the priest was called a *huamac*, but afterwards there was much specialization with consequent multiplication of names. The real doctor or *hampi-camayoc* was under an obligation to treat the Inca and his family and may even have been a member of the nobility himself.

Below him came the *ccamascas* or *soncoyoc*, who practised among the common people. There were many other grades, but there is a good deal of confusion in the use of their appellations by the old Spanish historians.

*Diseases.*—The sources of our knowledge of the diseases of ancient Peru are the examination of mummies by inspection, X-rays, &c., the representations in ceramics, and the accounts of the Spanish chroniclers, but the latter are, of course, confused by the imperfect diagnosis of the sixteenth century. Thus the devastating epidemic of about 1524, which killed the aunt, brother and sister of the Inca Huayna Capac whilst he was in the island of Puná and killed the emperor himself at Quito on his way back to Cuzco, was thought by Cieza de León to be small-pox, and Lastres agrees, but Pachacuti was inclined to call it measles; in any case it was an infectious febrile illness with a papular rash and a high mortality. Some have thought that it was *verruga peruviana*, a peculiarly loathsome disease which has been common in Peru for many centuries. It is characterized by fever, anæmia and a widespread nodular eruption of the skin, and Zarate [18] says that this disease was more destructive than small-pox.

Clear evidence exists of rheumatic disease and Williams [14] found signs of vertebral osteoarthritis, probably of rheumatic origin, in a Peruvian mummy. Rheumatism was probably very common, the humidity of the climate in some of the agricultural and mining districts being favourable to it [12].

Malaria was undoubtedly common on the coast and in the coastal valleys and was called *chucchu;* whilst as for cancer the only certain evidence is given by the very rare examples of what was apparently osteosarcoma.

There is no doubt that epidemics were fairly frequent and often led to the abandonment of the towns in which they occurred, which were thereafter regarded with superstitious horror. This may well be the origin of the "lost cities" such as Machu Picchu.

Typhus must have been common. It had, apparently, always been endemic in the sierra and from time to time caused serious epidemics, especially in the rainy regions [12].

Warts have always occurred in the same regions, especially in the ravines, and were called *sirki*.

Respiratory diseases were ill-understood, but nasal catarrh, cough, and pneumonia were certainly known and pulmonary tuberculosis was probably not uncommon; its spread being favoured by the system of *mitimaes*, under which populations of doubtful loyalty were transplanted from their native places to other parts of the country.

Tuberculosis of the bones is well represented in ceramics in the form of Pott's disease of the spine.

Tetanus infection appears to have been frequent, especially in children, and was called by the Spaniards the "three-day illness".

The possible incidence of rabies has been hotly debated. It probably occurred sporadically.

Coming now to endocrine diseases, goitre has been the subject of much study and was described by Bartolomé de la Vega, Calancha, Cobo and other authors as being common in some districts, such as Cuzco.

Acromegaly and achondroplasia are represented in ceramics. The existence of true dwarfism and gigantism rests chiefly on legend.

Artificial eunuchs were made by some of the tribes in pre-Inca times and according to Blas Valera the confessors in the Inca temples were either eunuchs or had sworn perpetual chastity.

Obesity is well represented in ceramics, and myxœdema is suggested by the descriptions of some of the Spanish chroniclers.

Of neurologic affections, deafness and deaf-mutism can be identified. Club foot, probably the result of an adult hemiplegia, is also represented, as well as facial paralysis and hare-lip (Fig. 2 (1) and (2)).

FIG. 2.—(1) Facial paralysis. (2) Hare-lip. (3) Multiple amputations. (4) Pruriginous skin condition. [Copyright.]

Eye troubles were common, such as gonococcal conjunctivitis, keratitis and perhaps trachoma. There are suggestions, too, of blepharitis, infectious panophthalmia, and tumours of the eye. Blindness appears to have been common but may sometimes have been inflicted in punishment. Epilepsy appears to have been commoner on the coast (among the Yungas and Mochicas) than in the mountains.

A curious complaint, called by the quechua Indians *taqui oncco*, or the dancing disease, has been described by Ondegardo and others and may be similar to the *tarrentism* of the Middle Ages in Europe, as it was cured by communal dancing.

There is good reason to believe that the use of coca, which was and is common among the Peruvian Indians, was not so harmless as some have maintained. Gutiérrez-Noriega [15] has found in such cases psychical and sensorial changes, modifications of visual and auditory acuity, auditory and visual hallucinations and alterations in time perception. In cases of serious intoxication there occur fantastic visionary effects, such as macroscopia, microscopia, distortion of image, and alterations of spatial perception, also thought changes such as acceleration of mental processes and obsessions.

The Peruvian Indians were not naturally a very cleanly people and it is not surprising, therefore, that skin diseases were common. Washing was, however, linked with their religious beliefs and the efficacy of water for cleansing from disgrace and sin was universally believed.

The *jigger* was a common pest, from which they protected themselves by wearing woollen sandals, or *uxuta*, whilst plasters made of the leaves of the *apichu* were used for killing this insect.

Ringworm and eczema appear to have been frequent and a pruriginous affection of the skin is shown in Fig. 2 (4).

Leishmaniasis, or *uta*, is endemic, especially in the foothills of the Andes. Lavoreria identifies this with the so-called "disease of the Andes" which attacked the Indians who went to cultivate coca under the Incas. Its corrosive action is noted and it is represented in

ceramics destroying the skin and producing facial disfigurement with destruction of the nose and lips.

The existence of leprosy in Peru is uncertain.

Pellagra may well have occurred in view of the almost exclusively maize diet of many of the tribes.

Genito-urinary affections: Cobo mentions retention of urine and the presence of gravel or stones in the bladder, but this appears to have been rare, perhaps because of the diuretic and calculus-dissolving action of chicha, the alcoholic beverage made from maize which is still so popular.

As regards the possible occurrence of syphilis Lastres devotes a whole chapter of his book to a discussion of the pros and cons. Whether syphilis was imported into Europe from Hispaniola by Columbus' returning sailors, or whether it existed in Europe and the Near East from ancient times, has been hotly debated on many occasions (sometimes in this Society) but I have no time to examine the evidence. It should be noted, however, that some of the Spanish chroniclers, writing soon after the conquest, stoutly defended the Peruvians from this charge.

Many skulls and long bones have been found in ancient Peruvian cemeteries with pathological appearances suggestive of syphilis, but the skull found by Tello and Williams [16] in Paracas in 1929 probably affords the most convincing evidence of the pre-Columbian existence of syphilis in Peru, and the word *huanthi*, in the quechua and amara languages, the most ancient of all the Peruvian languages, is believed to represent this disease.

Enteritis and dysentery were common, which is not surprising in view of their primitive hygiene and their consumption of raw vegetables.

Other bony lesions found, apart from those due to tuberculosis and syphilis, include exostoses, periostitis, necrosis and perhaps osteomyelitis. Moodie has described a tumour of the dura mater of the meningioma type.

## Surgical Treatment

Surgery was a very necessary art for such warlike peoples as the ancient Peruvians and Moodie says that no other race produced better surgeons, judging by the success of their operations. These surgeons were called *sirkaks*, and were probably distinct from the physicians. Their principal instrument was the *tumi*, of which many variants have been found, a crescentic knife usually of bronze and extremely sharp, with which the soft tissues were easily divided, though it may also have been used for trephining. Knives and plates of obsidian and of flint were also found by Tello in the necropolis at Paracas, as well as dressings of cotton-wool and of cotton thread, moulded to the shape of the original wound. As clips to hold the wound edges together the Indians employed the mandibles of a certain species of ant.

There has been a great deal of discussion as to the anæsthetic, if any, used at operations, but it seems clear from the testimony of Betanzos [13], supported by Tschudi's linguistic studies, that a stupefacient frequently employed, not merely for major surgical operations but also for ear piercing, was a special brew of chicha in which was infused the stalk of a fruit shaped like an almond and called by the Spaniards *espingo*. This drink was called *sora*.

Mutilations, including amputations of feet, hands, nose, and lips are frequently represented in ceramics and are often multiple (as in Fig. 2 (3)). Their origin and purpose are, however, still uncertain. Apart from those which might be due to leishmaniasis, leprosy, &c., there are many which seem to be artificial and were probably punishments for legal offences.

Fractures and dislocations were often attributed to the violence of a spirit inhabiting the body and were therefore treated by sacrifices and offerings on the spot where the trauma occurred, but more effective was the setting of fractures, with a paste containing coca, salt and white of egg which set hard and acted as a splint [12]. Operations performed included enucleation of the eye, reduction of large hernias, and castration [17].

A pre-Inca skull in the museum at San Diego, California, has fastened to it an apparatus in perfect condition, which appears to have been devised for controlling bleeding from the scalp. The portion of this apparatus passing over the vertex is wrapped in cotton-wool covered with gauze, stained in places with what appears to be blood. Most remarkable of all, the cotton-wool is soft and white and the gauze of finer texture than is made to-day. This was more than 1,000 years ago.

Suction and massage were used for surgical treatment and the *hechiceros* said they sucked the wounds so as to suck out blood and with it the disease [4]. This treatment was effective for reducing hæmatomata, extracting foreign bodies, arrows, and fragments of bone, and for relieving pain. The Indians believed that all inflammation was due to a foreign body, either visible or invisible.

Trephining in ancient Peru has received a great deal of attention and I have space only to give a brief outline of our knowledge of this subject. I have already referred to the *tumi*, the knife used for trephining as well as other operations. Fig. 3 shows a *tumi* bearing on

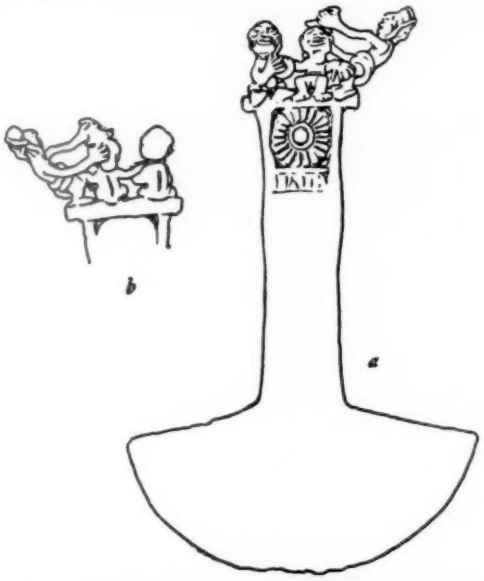

FIG. 3.—Tumi, bearing on the handle a representation of a trephining operation (after Antze). [Copyright. Reproduced by kind permission of the Director of the Museum für Völkerkunde, Hamburg.]

the handle a representation of a trephining operation, giving a very good idea of how this instrument was used. This *tumi* is of metal, but *tumis* of stone and obsidian were also employed in some early cultures.

There is much difference of opinion as to the object of this operation, but owing to the frequency of skull injuries among these warlike peoples symptoms such as epilepsy, due to compression or irritation of the brain, must have been common and were probably attributed to the presence in the skull of a restless spirit wishing to escape. Thus trephining might be expected to be used in such cases, as well as for symptoms due to other forms of compression or cranial disturbance, such as tumours of the brain or its membranes.

Many different methods appear to have been employed. A *tumi* with a crescentic edge would seem to be quite unsuited to cutting through the bone of the skull [19], without fatal results, and it was therefore probably used only for dividing the soft tissues, and when Callo and Quevado [20] carried out their astonishingly successful trephining with ancient Peruvian instruments in the hospital of Belén in 1944 they had to abandon the *tumi* when they came to bone and proceed using knives of obsidian and flint. Other methods seem to have included scraping with flint, obsidian, quartz or instruments of copper or bronze. The incisions in the skull were in the form of a square, a triangle, an oval, &c. Trephining by drilling was also employed, and one skull has a gold prosthesis inserted after a frontal trephining.

Neolithic trephining seems to have been rather haphazard and must often have been fatal, but the careful avoidance of the longitudinal sinus in two skulls testifies to a better anatomical knowledge and skill at a later date. Perhaps the most remarkable feature of the whole thing is the number of cases, as shown by the smoothed edges of the holes, in which the patient survived, not merely a single trephining but as many as three! Patients who survived trephining were apparently regarded as specially endowed with supernatural powers.

## OBSTETRICS

Childbirth, according to Garcilaso, seems usually to have been easy for the Peruvian Indians, for he says that directly afterwards, having washed themselves and the

babies in cold water, they returned to their housework as if nothing had happened. But there can be no doubt that they regarded it with respect and even fear. The earth was thought to be the special protector of women in childbirth and they sacrificed to it [10]. They burnt clothes to it, buried ewes alive, sacrificed maidens, and with the hearts of ewes they sprinkled blood to the Sun. Confession and purification were practised by the pregnant woman and in many of the tribes, including the Incas, the husband did so too and also fasted when his wife was at term.

The arrangements for the delivery are well shown in Fig. 4. The woman is seated naked

FIG. 4.—Childbirth. [Copyright.]

[Figs. 1, 2 and 4 are reproduced by kind permission of Professor J. B. Lastres.]

and legs apart on a low stool, or perhaps a filled sack, supported behind by her husband with his arms locked round her and attended to in front by the midwife.

The practice of abortion was common in pre-Inca times, but the Emperor Pachacutec forbade it under heavy penalty. Once again the Incas showed their enlightenment. In contrast the Arma tribe, who were cannibals, used to take women at about term, slit up their abdomens with great skill and speed, using knives of flint or bamboo, and extract the babies for eating [7].

## MEDICAL TREATMENT

The first thing to remember when considering the treatment of disease is that it had a magical basis and that in the mind of primitive man drugs acted not by their intrinsic merits but because they were the vehicles of a benign spirit.

The remedies employed can be divided into animal, vegetable and mineral. Of the minerals gold, in the form of an infusion, was used to treat epilepsy; silver, applied to contusions, prevented ecchymosis; magnetic oxide of iron in the form of powder dissolved in water, was used to treat nervous and cardiac affections; *ccolpa* or *millu*, a flux, was used as a purgative, as a liniment, as a caustic for ulcers, and in the procedure known as *millipña* or *ccolpasca;* sulphur to combat "air in the head"; lead sulphate, or *hancu-ccollque*, dissolved in water, for shock; orpiment or realgar for poisoning; *greda*, or emetic clay, to arrest

| | | Phosphorus | 2 |

Dr. Boucher continued by saying that a great deal of publicity had been given to this subject through films, the radio, television, leaflets, women's magazines and, last but by no means least, The Royal Society for the Prevention of Accidents. This publicity was bringing results, but more needed to be done through general and personal education, particularly of parents of young children, and of older children themselves. It was the personal influence of the general practitioner, the medical officer of health, the hospital doctor, and their agents, the home nurse, home help, and health visitor which must ultimately prove effective.

**Mr. D. MacG. Jackson** (Birmingham): Basic fact-finding work, which is the foundation of accident prevention, is being carried out in this country largely by the Royal Society for the Prevention of Accidents, by the Ministry of Health, different Government Departments, the British Standards Institution, the Fire Research Board, the Fire Protection Society, the police, and by interested individuals, several of whom have been doctors. In 1956, the World Health Organization formed an Advisory Group on the Prevention of Accidents in Childhood to study methods of fact-finding, and to evaluate and co-ordinate related data. Their first report makes most interesting reading and should certainly be read by doctors working with children (Accidents in Childhood, 1957).

The general principles of accident prevention are conveniently classified in this publication under the three internationally accepted E's—Education, Engineering and Enforcement by regulation and law. "Education" includes the training of children and the teaching of parents. It also includes making drivers of motor vehicles aware of special risks and keen to drive with a high standard of care. "Engineering" includes not only improving the design of houses and roads to prevent accidents, but is a convenient heading under which to include all changes in design and manufacture of cars, furniture, clothes and toys, to make them safer. Only when propaganda, the provision of facilities and public opinion fail to get safety measures accepted is "Enforcement" by legal measures necessary. But where continued inertia and economic considerations encourage a laissez-faire attitude, legislation may be the only effective measure.

The three chief causes of fatal accidents in childhood in England and Wales are, first, motor vehicle accidents, followed in frequency by burns in girls and drowning in boys. Other accidents in the home are less lethal to children but much commoner, and include scalds, falls out of bed, off furniture and on stairs, and injuries by domestic machinery and from doors. The following is a brief survey of adopted and suggested preventive measures for two of these types of accidents, namely motor vehicle accidents and burns, mentioning only those features which are related to child accidents.

## MOTOR VEHICLE ACCIDENTS

In 1956 there were more road vehicles licensed in Great Britain and more people hurt on the roads than ever before, but there were fewer child fatalities than in any year except 1954. The main contributors to this decrease were child pedestrians (Road Accident Statistics, 1956). However, there are still nearly 50,000 children becoming road casualties each year.

*Education.*—Fig. 1, shows the period in life during which a child is at great risk as a pedestrian (3–12 years), and as a pedal cyclist (12–21 years). This emphasizes forcibly the importance of training children from a very early age in how to behave as pedestrians in modern road traffic, and this should later be extended to how to cycle on the road. The responsibility for training falls primarily upon the parents and upon schools, but many organizations are playing a part. A game called "last across the road" used to be played in this country by school children and consisted in dashing across the road in front of oncoming traffic, the smaller ones sometimes falling and becoming casualties. This dangerous game has been practically eliminated by preventive instruction in schools (Accidents in Childhood, 1957). The "Mind that Child" Campaign, September–November 1956, is claimed to have played a part in making 1956 the second lowest annual total of child road deaths on record; and last year the "Road Safety Matters" Campaign was conducted throughout the country. There have been many local campaigns of which the Slough Two Year Road-Safety Experiment has probably been the biggest.

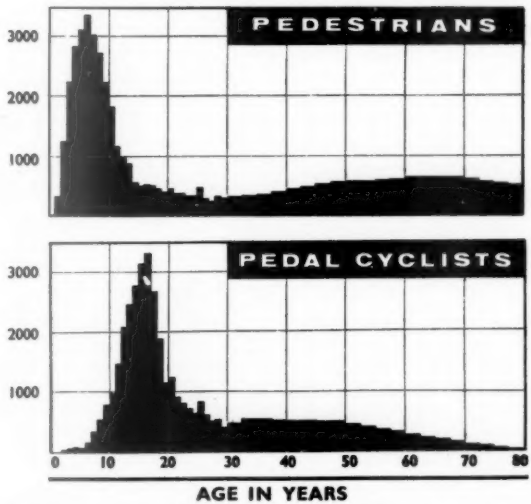

FIG. 1.—Pedestrian and pedal cyclist casualties according to age in 1956. (From Road Accident Statistics, 1956 (1957). Royal Society for the Prevention of Accidents. By courtesy of the Editor.)

If parents are to train their children, they too must be made aware of the risks their children run on the road. The Press plays a big part in this education programme whenever a news item presents the opportunity, and much useful propaganda is also absorbed from radio and television programmes. B.B.C. Television, which at peak times reaches 1 in 3 adults in Great Britain, is very alive to the problem. Recently in 77 days there were 61 items of road safety interest. Again, short film flashes between main features at the cinemas can be a most impressive reminder in graphic form.

The education of drivers is a much more subtle business, for every man will claim to be an expert driver if he is more than ten miles from home. There are at least two ways in which a driver may have impaired judgment and ability, *without knowing it*. The first is the ill-understood phenomenon of skill-fatigue. The following description of it appeared in a recent *Lancet* editorial (*Lancet*, 1957*a*). "In the driver its earliest symptom is a slight change in the timing of his reactions. . . . Classically the night driver halts at an intersection where there is no traffic light and waits patiently for the green; then, 'pulling himself together', he flashes on, intent on the clear roadway ahead, and deriving no meaning from the headlights he sees approaching from the side." Skill-fatigue is not necessarily accompanied by physical tiredness, and in fact most road-transport accidents occur in the first three hours of the journey. Awareness of the entity of skill-fatigue should make those who know about it more careful and more safe.

Alcohol is the other serious cause of impaired driving standards, and again I quote from the same editorial (*Lancet*, 1957*a*). "Controlled studies in Sweden have shown that very small quantities significantly increase driving errors committed even by first-class motorists. Indeed much driving experience and a little alcohol may be one of the deadliest combinations. It is also worth bearing in mind that, though rapidly absorbed, alcohol is eliminated from the body very slowly, and that it may linger in relatively high concentrations in the cerebro-spinal fluid and in brain-tissue many hours after the blood-alcohol level has returned to normal. (Most airlines require that pilots shall abstain from alcohol for at least eighteen hours before flying.) None of the popular remedies—exercise, a cold bath, strong black coffee—has the slightest effect on the slowed reactions, impaired judgment, and lack of insight of the alcoholic driver." I do not know the incidence figures in this country, but in the U.S.A. in 1956, 40,000 people died in road accidents and "a drinking driver" was involved in 30% of these fatal accidents. 20% of all pedestrians killed were reported as "had been drinking". (Road Accident Statistical Review, 1957.) The meaning of these terms is uncertain, but even if a causal relationship is established, can people be persuaded to accept the general rule "I don't drink before driving"? Public opinion varies in different countries, depending in part on the value put on personal liberty and the safety of others.

*Engineering, design and manufacture.*—Most changes contemplated in this field at present are of general preventive value and include children only incidentally. Much work is now going ahead on the improvement of roads and the provision of bridges, islands and crossings. Separate cycle tracks—such a good feature on many continental roads—should surely be provided more often in this country, and their use by cyclists made compulsory. One hopes that improvements in car design will really materialize from the findings of the Cornell University team. Features of car design at present responsible for fatal accidents to passengers, including children, are lack of safety belts, accepted long ago in air travel, and inadequate safety-locks on doors to prevent ejection from the car in roll-over and other accidents: severe-to-fatal injuries were four times less common in road accidents in a group of cars provided with safety belts than in a comparable group without (*Lancet*, 1957*b*). Other changes in car design to improve vision, especially where the windscreen and driver's side-window join, and better seat adjustment to include elevation as well as forward and backward movement are called for. Safe dipping and antidazzle arrangements are a common topic for criticism and suggestion in the daily papers at present, and dashboard layout seems often designed more for symmetry than for safety. To switch off the headlamps at night by mistake for 1 second, while intending to light a cigarette, means driving blind for 60 feet if the speed of the car is 40 miles per hour.

*Enforcement.*—In this democratic country in peacetime controls are only initiated and accepted when public opinion is ready to accept them. This has advantages in reducing the number of regulations but it makes for slow progress in reducing accidents. Limitation of parking for a safe distance before pedestrian crossings has been accepted without difficulty. So has the closure of some unessential streets to traffic in thickly populated areas, so that they may become the safe and only playground of the many children whose houses open on to them. Is it time yet to legislate to prevent all traffic parking on a country road? In the United States all traffic parking in the country must get off the road. Again, should parking be prohibited within 30 yards of a road intersection *everywhere* (Gissane, 1954)? Would compulsory use of pedestrian crossings with red and green lights in all built-up areas be regarded as impossibly harsh? At present, almost certainly it would. Should child cyclists have regular cycle inspections at school or by the police? Sometimes one sees children riding pillion on motor cycles without crash helmets. Crash helmets reduce the chance of head injury in an accident by 30–40%, and the wearer has a 50% better chance of survival in non-built-up areas, and a 25% better chance in built-up areas (Road Accident Statistical Review, 1957). With this evidence should crash helmets not be compulsory? Fact-finding studies are called for first to confirm the size of these risks, and enlightened legislation may then be required to secure adequate protection from them.

## Burns

It should be remembered that children are the group most seriously affected by burns. At the Burns Unit in the Birmingham Accident Hospital, over half the domestic burns and scalds serious enough to be admitted are children under 15 years, and one-third are under 5 (Colebrook *et al.*, 1956). Again, a study of burns in which clothes were set alight provides the following comparison, after correction of age groups for population. If the incidence

of clothes-alight burns in adults from 15–64 years is taken as a standard, then children from birth to 4 years have ten times as many burns, and schoolchildren from 5–14 years six times as many (Bull, 1958).

The Registrar-General's figures of deaths from burns and scalds for 1956 show 741 deaths—a drop of 8 below the average figure for the period 1952–56. There were 11 fewer deaths from burns in childhood in 1956 (134) than in the previous year (145), but although this is in the right direction it is of doubtful significance. There has been little change in this picture in recent years. It is still true, as the *Lancet* wrote in 1946, that "in the homes of the people we neglect the most elementary precautions against accident, and wantonly permit hazards that would cause a public scandal in the most primitive factory or workshop".

The preventive measures that should be taken can again be considered under the three E's.

*Education.*—Tempest has demonstrated recently the appalling ignorance of parents, medical students, doctors and nurses about the risks of inflammable clothing and their responsibility to guard fires (Tempest, 1956).

Unguarded fires are the commonest cause of domestic burns and together with inflammable clothing are responsible for the great majority of fatal burns in childhood. The facts to be driven home in the minds of parents are:

(1) Adequate fireguards are the first step towards making the home safe from burning accidents. The guards should pass the British Standard Specification and should be capable of being securely attached to the fire-surround. Parents should be told where these can be purchased and how much they cost. Exhortations without this information carry little weight.

(2) Parents should know that if their child under 12 years suffers serious injury or death through burning or scalding due to an open unguarded fire, they can be prosecuted and fined up to £10. This adds a further incentive to do something without delay.

(3) They should know that by law all new gas, electric and oil heaters sold after October 1, 1954, must be fitted with a guard which complies with special safety specifications, and, probably more important, that safe guards can be bought for the old fires which they had before 1954. Again they need to be told where these can be obtained and the cost of them.

(4) Some Local Authorities hire safe guards to parents of young children. Where this applies it needs, of course, to be made widely known.

Tempest's study showed that sound radio and television programmes were by far the commonest sources of information in the case of parents who knew these facts. Other means of education used in Birmingham are regular reporting of burning accidents by the Press, film flashes in cinemas between features, warning posters in buses, exhibitions by the Royal Society for the Prevention of Accidents, lectures to Women's Institutes by doctors, nurses and others, the distribution of warning and information leaflets by health visitors, and the display of photographs of burned patients, with captions, in street windows by the Fire Service. Many people have fireguards, of a kind, which are rarely used, so that constant reminding *to use them* is valuable.

The second educational measure is to spread knowledge about the safety and dangers of certain fabrics. Clothing alight is a feature of half the burns admitted to the Birmingham Burns Unit, and it is a feature of four-fifths of the deaths. Nightdresses and dresses were about equally responsible in Tempest's study, loose-fitting clothing which stands away from the body being much more dangerous than pyjamas.

With regard to clothing materials, the information that parents should be given is that:

(1) Flannelette and winceyette, like other forms of cotton and rayon, are very inflammable. These materials, being cheap and attractive, account for four-fifths of the clothes-alight injuries and nine-tenths of the clothes-alight fatalities. Wool and silk do not burst into flame in the same way, but smoulder. Man-made yarns like nylon and terylene are inherently safe, and are marketed in many attractive forms and designs.

(2) Some materials which burn easily, such as cotton and rayon, can now be rendered relatively flame-resistant by chemical processes which withstand repeated washings and are not toxic if sucked by children. The efficiency of the process is established, but until recently there has still been some impairment in the texture of lighter weights of material.

(3) Some less-used materials are particularly inflammable. In New Zealand recently public opinion was shocked by the death of a well-known physician's wife whose ball dress of highly inflammable lacquered net touched an unguarded electric fire. Another new and particularly dangerous material is composed of waste fibres bonded together with latex; this is claimed to be suitable for stand-out petticoats under full skirts and is highly inflammable. The flammability of any material can be tested using a small piece from the seam of the garment.

Propaganda pressing home these points must be continued and pointed. Leaflets and posters can be displayed in Infant Welfare and School Clinics. Sixth form girls at school should themselves be taught the preventive measures for home accidents, and they should see displays of safe fireguards and safe fabrics with the names of shops where they may be bought.

*Engineering, design and manufacture.*—There is immense scope in this country for improved house design, especially in relation to heating; but while open fires continue to be used there will be no safety without the regular use of efficient fireguards, and these are available. But efficient fireguards need firm attachment to the fire surround, and in spite of recommendations for this by the Minister of Housing in 1949 few local authorities have so far provided such fitments in their new council houses.

Overcrowding is a fundamental contributory cause of home accidents, including burns, which can only be reduced by increasing the number of good council houses; and linked with this should be improved kitchen design, particularly in the arrangement of the cooker and sink, so that boiling water does not have to be carried across the crowded living room several times a day.

On the textile front, firms should be encouraged continually to produce an increasing range of safe fabrics, using inherently safe materials at present, and, when perfected and available, flame-proofed cotton and rayon also.

A large degree of safety can be obtained simply by dressing girls in pyjamas rather than nightdresses, and at least one large national store has stopped selling nightdresses for this reason. Others should be encouraged to follow suit.

*Enforcement.*—The prosecution of parents and guardians whose children under 12 are seriously injured or die due to unguarded fires is not often carried through. After a warning it is usually felt that they have suffered enough and have learned their lesson—although too late.

Apparently no legislation exists to prevent the import or manufacture of extremely dangerous materials, such as lacquered net, or to ensure that buyers are warned of their danger. As soon as a workable standard is accepted by the British Standards Institution it should be possible to mark material with its flammability rating, and this warning should be made compulsory.

It is to be hoped that the all-Party Parliamentary Home Safety Group which has been formed will attend to necessary legislation as new evidence of preventable risks calls for it.

If the fitting of efficient guards to old electric, gas and oil fires could be made compulsory, there is good reason to believe that many deaths and much suffering would be avoided.

The statistical and scientific approach is well suited to *investigation* of the accident problem, but it is useless to touch the hearts of many people and to goad them to action. On the other hand, the tragic, individual case, with its peculiar hardships faced with quiet courage, is equally useless as a basis for planning wholesale preventive measures. But if the individual case is representative of common risks, and is well presented, it may kindle such deep concern in the hearts of hearers that parents will go out and buy a fireguard, and doctors will notice and speak out when they see children surrounded by needless domestic risks. Many decry the value of emotion to strike through indifference and inertia, but for many people emotion is a much more effective spur to action than intellectual knowledge and should be used as a good servant. It is a peculiar idea of intellectual integrity to believe one must use the same language and approach to the harassed mother and to the research statistician.

How can we "get through" to knowledgeable, influential, and good-hearted people who meet statistical data with the attitude "Accidents will happen!"—"You can't wrap children in cotton-wool!"—"We all have to learn the dangers of our environment the hard way." We need to enlist the help of the leaders of the textile industry, the retail trade, the electricity and gas boards, and local authorities. I believe we must show them injured children, in hospital or pictured, to clothe the statistics with personality and make them live.

Here are statistics—"Ten thousand children are severely injured on the road each year, and 700 more are killed". Now I want you to meet Janice (Fig. 2). She was 5 years old. She was knocked down by a car and her leg run over. She had to lose her leg. Did she have to learn her road-sense this way? If she had been your girl, would you have felt that a little teaching about road safety would have been "wrapping her in cotton-wool?"

FIG. 2.—Janice, aged 5. She lost her leg after being knocked down by a car. (By courtesy of Mr. William Gissane, 1954, and the Editor of the *Practitioner*.)

FIG. 3.—Dorothy, aged 5. Her clothes caught alight from an unguarded coal fire.

Or again, here is Dorothy, aged 5 (Fig. 3). Her cotton dress caught alight from an unguarded coal fire. She tried to get it off over her head but did not manage it. It burnt out. Her face is terribly scarred for life. Of course it could happen to any girl with a dress of inflammable material who was put to live in a room with an unguarded fire. But one cannot help wondering—Did she have to learn the dangers of her home environment in a way so costly, and so final?

Even disability and disfigurement do not always measure the full tragedy of a child's accident. Recent work in the Birmingham Burns Unit by Woodward (1958) has shown that out of 200 children admitted between 1952 and 1955 with burns of more than 10% of the body surface, 85% still show signs to-day of emotional and mental disturbance in the form of fears and anxieties, depression and lethargy, aggression or unsociability—sometimes with added psychomatic disorders such as enuresis and stammering. Some people are more touched by this aspect, as well they might be.

To most people children matter. For many accidents in childhood methods of prevention are to hand. What is the necessary ingredient which will change the still prevailing attitude "Accidents will happen" to the determination "Accidents won't happen"?

**Professor S. D. M. Court** raised the question of what was a "significant" accident. Referring to the Thousand Families Study in Newcastle he said they had come very near to Clements' definition of a significant accident as one that was serious or could have been serious in slightly different circumstances. In the first five years of life the 847 children in the families had had 732 accidents accounting for 9% of their total illness; but only eleven were admitted to hospital. About half the accidents were falls, one-sixth burns and scalds and the remainder divided equally between "crushing", "traffic" and miscellaneous injuries. They had been unable to demonstrate any special risks or personal proneness to accidents which were not explained by differences in sex, living conditions and maternal care. Propaganda addressed to parents and children, though necessary, he thought more limited in its effects than generally realized. If child protection was to become part of the structure as well as the attitude of society, it should be addressed primarily to the designers and manufacturers of houses, fittings, clothing and all potential dangers in the environment of children.

CLEMENTS, F. W. (1953) *Med. J. Aust.*, i, 348, 388, 421.

**Dr. L. Colebrook** agreed with a previous speaker that the public was often misled by the labelling of a material, or a garment, as nylon (a relatively safe fibre) when in fact it was a mixture of nylon with cotton or another more flammable fibre. It would be an important step towards safety if all clothing materials and garments were required by law to carry labels stating correctly their composition. The public was becoming more safety-minded. It would soon learn which materials were relatively safe, and which dangerous.

**Dr. D. MacCarthy** said that when a serious accident happened to a child there was at the same time an accident or at least a danger to his developing personality. Here was a field of prevention if treatment could be begun straight away. But the difficulties of going about it, say in a 2-year-old severely burnt child, were admittedly great. Did anyone know how to go about it? Was anyone doing it?

## DISCUSSION: EARLY DIAGNOSIS AND CANCER EDUCATION OF THE PUBLIC

**Mr. Malcolm Donaldson** [*Abstract*]:

To obtain early diagnosis in malignant disease is largely a psychological problem. True cancerphobia is rare but nearly 100% of the population suffer to a greater or less extent from cancer apprehension, which may take one of two forms: (A) Personal apprehension in which case the patient thinks "can this be cancer?" when a symptom is experienced which is not easily explained, e.g. a slight pain in a woman's breast. (B) Impersonal apprehension where a person fears that by speaking of the disease or even mentioning the word, fear will be caused in the person addressed. There is now overwhelming evidence in every country where cancer education is carried out, that this latter is NOT true. In spite of this many doctors in this country suffer from "impersonal cancer apprehension" and this does untold harm by keeping up "hush-hush and a conspiracy of silence" which is largely responsible for the delay in seeking advice in the accessible cancers and these as a rule do show symptoms whilst the disease is still in an early stage. For example, the average delay after noticing symptoms in carcinoma of the rectum is thirteen months, uterus six months, and breast seven months. Figures published recently by the Registrar-General show that six months' delay reduces the number of early-stage cases from 71·6% to 46·7% which means the loss of thousands of lives.

*Statistics.*—Positive statistical evidence of the value of cancer education is very difficult to obtain for many reasons, e.g. the fact that such education is discouraged by doctors in this country, and that the clinical records are inefficient in most hospitals. There are other difficulties; for example, the unknown factor of the rate of growth and malignancy in any individual tumour. This shows itself if the five-year survival rate is used as a criterion as is seen in the following figures from Manchester:

| *Delay in months* .. | 0–3 | 4–6 | 7–12 | 13–24 | 24+ |
|---|---|---|---|---|---|
| *Five-year survival*.. | 44% | 39% | 41% | 39% | 44% |

This, of course, is a comparison of entirely different types of growths. In the early months the majority of tumours are rapidly growing and highly malignant, whereas after two years the growths are entirely slow-growing almost benign tumours, a selection by death. This difficulty of the "unknown factor" can be largely avoided by comparing the records obtained over many years, of the delay in reporting certain symptoms, e.g. lump in the breast, uterine bleeding, rectal bleeding, &c., *whatever the cause of the symptom*, and the percentage of "early stage cases of cancer" treated during the same years of cancer education. If the delay diminishes and the percentage of "early stage" cases treated increases, then there can be no doubt of its value. Figures obtained from Canada and elsewhere are very suggestive of the value of cancer education.

*Attitude of public to cancer education.*—The public are interested in the subject of cancer and lectures are popular. 74 were given in the Oxford area with an average attendance of 3[illegible]·2 per lecture during 1947 and 56 are booked for 1958. In Yorkshire of 5,740 ballot papers filled in at the end of lectures 99·1% voted in favour of more lectures, 0·2% against and 0·7% put a ?.

*Reaction of medical profession.*—Result of British Empire Cancer Campaign questions to all general practitioners 1953: Only 24%–25% replied and of these 2,683 voted against, 2,370 voted for Cancer Education. Few have had any experience, and many are very prejudiced.

*Method of carrying out cancer education.*—Word of mouth is the best; lectures by doctors, but these can only be few. Information passed on by nurses is the only practical method; they are the first line troops of any campaign. Other aids are pamphlets, page-turning machines, films, &c.

## Conclusions

From the psychological point of view cancer-education is of very great value to the nation and will save a number of lives. It has well been said "It is better to die of cancer than to live in fear of it", but it is better still to do neither.

"Knowledge is the antidote to Fear."
*Emerson.*

**Dr. John Burton:**

In the last ten years since I have been engaged in Health Education, cancer control has been an ever-present problem. Clinical statistical evidence and the behaviour of surgeons has caused me to assume that cancer control can be based on prevention and early treatment.

In the gynæcological field there are very few clues to prevention. As one whose job it is to help people to help themselves, my interests have been centred on early treatment.

It is generally the patient who makes the first diagnosis; the patient and friends who decide what to do about it, whether to visit a doctor or a quack or neither. It is the patient and friends and even employers who decide whether she will accept treatment and carry it out. The medical profession is remote from these decisions. The events I am most interested in are those which take place within the bosom of the family in casual conversation, concealments, and reticent understatements and in rationalizations of committees responsible for treatment or disseminating information.

Apart from any measure of environmental control which may be profitable, most promising lines of cancer control involve some major change in human behaviour, which, of course, means education. For the public health world the problem of cancer control is one of environmental control and education. It is education of the medical profession, of Members of Parliament, of public men such as councillors and also of the general public. The attitudes of optimism or despair, and the feelings of confidence or fear in such people may be an important determining factor in whether anything is achieved.

The outstanding problem to be faced is the emotional climate in which this disease exists: the fear of fear: it constitutes a major resistance to doing anything in committees and we have seen it obstructing in all sorts of organizations which should know better. For many years the official view of the Ministry of Health was that cancer education should not be carried out, for fear of creating cancerphobia in the public.

What we have done is to shift our own fears on to the shoulders of the long-suffering public and say that it is they who are frightened when really it is ourselves. We have met the same problem in the medical profession, and a recent vote of general practitioners on the subject of cancer education registered a 50–50 for and against. We have come across the same problem in research organizations which will not touch the subject of cancer education. Every argument has been used to avoid public discussion on this fearful thing.

We have not, curiously enough, met this fear of fear among the populace. I have addressed many ordinary meetings and given information about cancer and the reaction has been "What is all the fuss about?" "Why are people going around with long faces and behaving as if this were something special?" The general public, on the whole, are much more prepared to accept Clough's paradox "If hopes were dupes, fears may be liars" than we are.

The individual reasons encountered for doing nothing are to regard the whole matter as something distasteful or which "couldn't possibly happen to me". The childish hope that symptoms, if ignored, will pass away, is also encountered. There are also those whose self-respect is bound up with not having a day's illness, and some even seek relief in regarding cancer as a punishment for bad living and an expiation of guilt.

The suggestion has been put forward that special clinics should be set up like the tuberculosis clinics, where people could drop in almost secretly and have an examination. This is something that the Health Service may have to bear in mind in any planning—that it is no use having cancer education if people do not feel happy about the place where they have to go to declare their symptoms.

*What positive steps can health workers take in education?*—First we must be sure that the story we tell is true and, in accordance with the Hippocratic oath, does no harm to our patients. We must be satisfied that cancer education does not cause cancerphobia and that the information we put forward is well backed up by evidence.

In the case of prevention there are already sufficiently well established facts on which to base action. There is strong evidence that the personal hygiene of the husband plays an important part in the risk of cancer of the cervix in the wife. The connexion between smoking and lung cancer is well established. The case against atmospheric pollution is a strong one, as is also the case for breast feeding in the prevention of cancer of the breast. X-raying pregnant women appears to increase the risk of their children developing leukæmia.

In relation to early treatment, we are not yet in a position to be dogmatic, because there are still two main points of view between which we have to choose. The first proposition contends that there is, as yet, no satisfactory evidence that cancer treated early does better than cancer treated with delay, and that therefore however effective cancer education may be in cutting down delay, the end-results are the same. If this argument is carried to its logical conclusion it must mean that treatment at present given is worthless. The only sensible thing to do would be to pack up, save the money and spend it on research. In practice, however, I have yet to meet the surgeon who does not try to get his patients as early as possible.

The other more hopeful proposition is that cancer in certain sites definitely does better when treated in the early stages. The sooner patients see their doctors after noticing something wrong the more likely are they to be cured.

That two such diametrically opposed hypotheses can exist raises the question: Why has the Medical Research Council, or some similar research body, not yet been asked to test these opposite assumptions on which the lives of upwards of 80,000 people depend each year? We appreciate that it is not easy, but the problem is of such magnitude as to warrant the utmost effort. Research work will have to be done which they should commission. Ideally it should seek to establish, firstly, the degree to which early treatment affects the chances of cure; and secondly, the effectiveness of education in causing people to take certain symptoms to the doctor early.

The first aim can only be achieved if experiments are designed specifically to reveal the relationship between early stages of the disease and early recognition by the patient. The second can only be demonstrated if general practitioners are prepared to make a special enquiry and record of anyone complaining of certain designated symptoms whether they turn out to be cancer or not. Any one, or any group of symptoms, can be chosen for education and recording, and a before-and-after study carried out. Some well-placed authorities consider that such experiments would be too difficult to interpret and that finally the only useful experiment would be an educational programme followed by an assessment of any changes in cancer mortality.

**Mr. C. J. Thurgar:**

In the past the advocates of education of the public regarding cancer have, in my opinion, tended to make rather optimistic claims for improvement in the survival rate if the disease is recognized and treated within a short time of the appearance of the first symptoms. It is equally true that opponents of cancer education appear to have exaggerated the danger of increasing the incidence of cancerphobia. I include myself in those who have set their hopes too high and have claimed too much. I first became interested in cancer education in 1936 and started with some of my colleagues in Newcastle upon Tyne a programme of lectures to lay audiences, large and small. It was soon found that large meetings were not a success and our efforts were concentrated on Women's Institutes, Rotary Clubs and the like. Several hundred such talks were given in the ensuing two or three years before the outbreak of war and in 1939 a booklet was published on the early diagnosis of cancer by the North of England Council of the British Empire Cancer Campaign. At the beginning a large number were sold but the sales rapidly tapered off and apart from distribution at meetings and talks, it was withdrawn in 1940. Two mistakes were made in the conception of this booklet. It included an appeal for donations to cancer research and it claimed too great a success in the sense of cure from early diagnosis and treatment, both in the number of sites of malignant disease listed and in the survival rates expected. The talks to small gatherings have been continued on a much reduced scale over the intervening years and have been well received as is shown by requests for repetition to the same groups after the lapse of an interval.

It is difficult to gauge whether these efforts have had any effect in North Eastern England of either a beneficial or a harmful nature. My impression—and it is only an impression—is that patients have occasionally consulted their doctors at an earlier date than otherwise would have been the case, but such information is very rarely volunteered either to the general practitioner or to the consultant. No instances of the production of cancerphobia have come to light and my experience is thus in line with that of other workers in the field of cancer education. In retrospect it appears to me that our programme was too widespread and lost some of its impact because we did not invite the co-operation of the general practitioners of the area.

Increasing familiarity with the natural history of the cancerous group of diseases and study of the mortality figures for our own population of 3 millions lead me to conclude that only a very limited field is available for honest and optimistic education. Healthy people do not want to talk or think about illness, which they may view with interest but not normally with personal concern. The fear of cancer, although emotional rather than rational, is

based on reality. The death-rate as a whole is rising, though there are wide variations in the mortality with the site of the primary tumour. How then, should an educational programme be planned to take account of these factors? It can be directed to three aims; the prevention of the development of cancer, the early diagnosis of those who have symptoms and the detection of cancer and precancerous conditions in the population as a whole before symptoms have appeared.

The prevention of cancer, apart from its industrial applications, is not fraught with great hope. We are not rational beings and I myself continue to smoke large numbers of cigarettes despite my full recognition of the possible hazard. A surgical colleague said to me "I should hate to give up smoking and then die of carcinoma of the rectum!" Far more people give up smoking for economic reasons than because they are concerned with the possibility of developing lung cancer in twenty or thirty years' time. To exhort women to feed their children on the breast rather than the bottle is similarly liable to consideration in terms of expense or expediency rather than of long-term prudence.

Early diagnosis of those with symptoms is in practice limited to sufferers from the accessible cancers—the skin, tongue, mouth and throat, breast, uterus and to some degree bladder and rectum. The bladder and the rectum are sites where education could perhaps best be directed as much or more to the medical profession than to the public. Skin cancer is not nowadays a real problem nor a contributor to mortality figures and squamous carcinoma of the head and neck and particularly of the tongue and mouth, has declined in incidence to nearly half of what it was twenty-five years ago. There is room for education here, but its effect will not be great in numerical terms.

Diametrically opposed views have been expressed very vocally in recent years regarding the effectiveness of treatment in breast cancer, ranging from the statement that it has *no* effect to claims that 75% of women could be cured if they presented for treatment while their growths were small and limited to the breast. The prospects of increased survival from early treatment can be gauged from the figures just published from Birmingham, where 49% of patients who were treated within one to two months of their first symptom, irrespective of stage or grade, were alive and well at five years, whereas only 39% survived five years if they delayed for six to eleven months. After one year, there was little variation in the survival rate. It may be that in cancer of the cervix uteri, an improvement of more than 10% would be found, but I have no reliable figures and the incidence of cancer of the cervix is only half that of breast cancer.

In my own regional figures, cancer of breast and cervix accounts for about one-sixth of the total incidence of malignant disease. There are 90,000 deaths annually in England and Wales from cancer and if one-third is added to cover successful treatment, probably an optimistic figure, an incidence of 120,000 per annum results. One-sixth of this is 20,000 and ten per cent of that is a gain of 2,000 women alive and well at five years. A considerable proportion of these would die from recurrence of growth after five years but the gain would still be very substantial. An additional 1,000 men and women could probably be salvaged from the many other forms of cancer by effective education on a national scale. I regard this hypothetical figure of 2,000 to 3,000 as a maximum and I doubt whether it could really be achieved. If it can, it is still no matter for great congratulation when set against 90,000 deaths a year.

There remains the possible trial of cancer detection clinics and mass screening techniques. Simple clinical examination of the mouth, breast, &c., either by the doctor or the patient presents few difficulties other than psychological ones, but most normal people would not want to be cystoscoped or be examined rectally once a year. The most hopeful method in sight at present lies in exfoliative cytology and this form of examination is most easily and reliably applied in the field of gynæcology.

In conclusion, it is my view that nation-wide and intensive cancer education, primarily to small audiences and supported by judicious press publicity, would have an appreciable effect in time upon the number of lives saved or prolonged, but the effort needed would have to be far greater and longer continued than is generally realized. In terms of its impact upon the total cancer death-rate, the effect would be comparatively slight. That is not to say that the effort should not be made, but too optimistic forecasts of its result must not be advanced until much better methods of early diagnosis and treatment are evolved than those at present available.

**Mr. John Wakefield:**

Much opposition to the idea of cancer education has sprung from the well-meaning, but vague, proposals put forward by enthusiasts. Doctors are not so much concerned to decide if cancer education is a good idea in principle; they want to know what its effects will be on them and on their patients. When asked to approve any proposed scheme of lay educatio

they must be told what information is to be given, how it is to be put over, and what safeguards are proposed against undesirable results. Only then can they assess the likely advantages and disadvantages of cancer education.

In the project conducted by the Manchester Committee on Cancer in Lancashire and Cheshire, every extension of the original pilot experiment has had ready support from all branches of the medical profession, once our proposed activities were explained and discussed in advance. A recent survey in the area where intensive education has been going on for six years (Wakefield and Davison, 1958) showed that the project had earned the almost unanimous approval of general practitioners.

The hub of the Manchester scheme is the panel of speakers—mostly specialists in the treatment of cancer—whose members give regular, short, informal talks to all lay groups in the area. There are no large public meetings, which tend to attract hypochondriacs and the unduly health-conscious, and stifle the easy flow of question and discussion. An article prepared by the Committee's staff reports each lecture in the local press. A supply of short pamphlets is sent to the secretary of each group shortly after the speaker's visit.

No general, and indefensible, claim that cancer is curable is made. Speakers emphasize the very good results of early treatment of the accessible cancers in women. They describe "warning signs" (not "cancer signs"), which always require a doctor's advice: lump in the breast, unexpected bleeding, a sore that does not heal quickly. None of these signs can be imagined, and all require investigation whatever their origin. Speakers are at pains to avoid fear techniques. Since fear has not made people seek advice in the past, there is no reason to suppose they would do so if their fears were magnified.

Great attention is paid to the manner of addressing the public. In the present climate of fear surrounding cancer, how one talks about it is probably as important as what one says. Speakers are advised on the technique of lecturing and the use of bright visual aids to add interest and make learning easier. Every effort is made to take account of existing prejudices and mistaken beliefs and to bear in mind that people's fears and emotions are deeply involved in their thinking about cancer. All the information given is honest; but the more hopeful and largely unknown side of cancer treatment is given some of the publicity that is its due. Brief recorded interviews with cured patients are played during lectures—with considerably more effect than the recital of percentage survival rates.

The need for some form of education is obvious. Rather more than half of all cancer patients wait more than three months after seeing symptoms before seeking medical advice. Therapeutic methods therefore have a fair chance of success in less than half the cases. There is pathetically little confidence in the efficacy of treatment when cancer is so generally believed fatal. The failures of treatment provide their own unhappy publicity; the successes go unsung, because few know of what they were cured, and fewer are willing to talk about it. Whatever the eventual effects of early treatment on the five-year survival rates, it is axiomatic that the earlier any disease is treated, the better. The primary need is to promote confidence in the value of treatment and to get cancer talked about as just another disease. It is now beyond all doubt that a carefully conceived and executed programme of education neither causes cancerphobia, nor adds to the work of general practitioners. Any propaganda that does so is bad propaganda.

## REFERENCE

WAKEFIELD, J., and DAVISON, R. L. (1958) *Brit. med. J.*, i, 96.

**Dr. E. V. Kuenssberg:**

As a General Practitioner it has been brought home to me that patients are realists, particularly in the absence of pain. They consider their symptoms and signs in relation to the likely interference with their life and function and responsibilities. If an abnormality does not cause much discomfort the thought that there may be absence from work, with loss of earning, is more important to the patient than is usually realized.

Some of the principal points we have learnt as being of great importance in another field of medicine, namely tuberculosis, where early diagnosis and public education have also been a problem, are the following:

(1) Speed with which diagnosis can be made.

(2) Availability of treatment.

(3) Patients will not come forward even for diagnosis unless they know that some means of financial help will be available should they be found to be suffering from the "dreaded disease".

One of the most important lessons from this is that it is high time we paid more attention to speeding up the investigating or diagnostic proceedings. For instance the chest physician who has a day bed for his suspected lung cancer case, and who can do all his investigations,

X-ray, tomographs, bronchograph, bronchoscopy, including biopsy plus a general check-up that day, and have a consultation with the chest surgeon and radium or X-ray therapist that afternoon, can thus give the patient either a clean bill of health, or a programme for treatment including an approximate date for admission to hospital. This will do far more than the type of investigation which forces the patient to trail his increasing worries from hospital department to hospital department over several weeks.

The importance of giving the family doctor adequate diagnostic facilities must also be stressed.

In one particular field of cancer, early diagnosis may well be placed into the family doctor's hands. Professor R. Kellar of Edinburgh University, Department of Obstetrics and Gynæcology, has demonstrated that by inviting general practitioners to take cervical smears by the Ayre method, it is possible to detect early unsuspected cervical malignancy in approximately 15 per 1,000 women thus examined. This was done in collaboration with the College of General Practitioners, South-East Scotland Faculty, from where the full report will be published elsewhere. The cytological examination of the smears was carried out by Dr. A. F. Anderson and his co-workers at Edinburgh.

These cervical smears were taken during the ordinary consulting hours from:

(1) All women who presented themselves for post-natal examination.

(2) In women who had menopause problems, without histories necessarily pointing to any gynæcological disease.

(3) In women where a complete medical examination was indicated for one reason or another without again any obvious gynæcological complaint, or in women seeking advice on family planning.

The technique of taking cervical smears proved suitable for general practice and did not worry the patient and it has now become a valuable part of our diagnostic facilities which we would not like to be without.

Taking cervical smears is, of course, no substitute for a gynæcological opinion. It is a useful screening test of the clinically unsuspected women.

Data collected by my partners and myself show an impressive rate of positive smears for the women in the age groups of 30–40. If we can succeed in taking smears from the remaining women in our practice in those age groups we would take an important step towards early diagnosis of a malignant disease which has its full-blown clinical incidence at 45 years of age. The cost of not detecting early cancer or precancerous conditions is illustrated by the fact that of 4 women who were found during this survey in our practice with clinical signs of cancer, 2 are now dead, the remaining 2 having a poor prognosis, whilst the expectation of life of the eleven who have been discovered by means of cervical smears during the College of General Practitioners investigation must be considered infinitely better.

SUMMARY

(1) Speedy and decisive methods of diagnosis and treatment must be made generally available to gain the confidence of the patient and reduce the cruel, anxious time often at present associated with the diagnosis of cancer.

(2) Economic implications must be considered if patients are to come forward freely.

(3) The family doctor must be the fundamental guide in all diagnostic problems and be given everywhere good facilities for early diagnosis.

(4) The cervical smear method seems to be specially effective as a screening test when applied in General Practice.

(5) We cannot rely on mass education and propaganda alone, but must have an efficient and well-supported family doctor service.

**Mr. Linton Snaith:**

One of the problems involved in cancer propaganda was put to me very forcibly recently by a general practitioner friend of mine in the North-East of England. He pointed out that if a patient presented with disturbing symptoms, and he wished to make an appointment with a consultant he might have to wait two or three weeks and then after the appointment admission to hospital might be deferred for another three or four weeks. This seems to me to be a very relevant objection from the point of view of the general practitioner. If we are to achieve early diagnosis and treatment of cancer and offer the public such a service, one of our first essentials is the establishment of adequate out-patient consultations at hospital involving a delay of no more than a few days for making an appointment, and the provision of sufficient hospital beds for the immediate admission for investigation of any case presenting disturbing symptoms. We all know the difficulties, but it is no use urging the public to seek early advice if we are not in a position to furnish that advice immediately and to allay fears by immediate admission and investigation.

President—A. DICKSON WRIGHT, M.S., F.R.C.S.

[*December* 4, 1957]

## TRANSATLANTIC DISCUSSION ON ADVANCES IN CHEMOTHERAPY OF CANCER[1]

*Moderator for the American Team:* **Dr. Leandro M. Tocantins** (Philadelphia).

*Moderator for the British Team:* **Mr. A. Dickson Wright** (London).

**Dr. Leandro M. Tocantins** (Philadelphia):

Ladies and gentlemen of the seen and unseen audience and our confrères overseas: Chemotherapy now occupies the centre of the stage in the treatment of cancer. The leukæmias and lymphomas, even though some doubt whether they are forms of cancer, are being widely treated with chemical compounds. Every year sees a slight but definite advance. This afternoon in this country (and it is snowing very badly here, Mr. Dickson Wright), and this evening in London, which I understand is a classical foggy evening—a London fog—we and our British colleagues discuss the chemotherapy of cancer with special attention to the leukæmias and the lymphomas.

Our two countries have contributed a great deal to the development of our knowledge of these diseases. We should like, at this time, to salute the memory of Thomas Hodgkin, the adventurous and shrewd clinical observer who, 125 years ago, described the disease that bears his name. British physicians from Hodgkin to Sir Lionel Whitby have added much to our knowledge of the leukæmias and lymphomas. More recently British workers, some of whom are members of your panel, have played and continue to play an important role in the development of the chemotherapy of these disorders. We are privileged to greet and express our appreciation to Professor Haddow, one of the world leaders in the field of cancer chemotherapy, to Dr. Wiltshaw of the Royal Marsden Hospital, to my good friend Dr. Bodley Scott of St. Bartholomew's Hospital, and to our fellow hæmatologist, Dr. John Wilkinson of Manchester. We are fortunate in enlisting the co-operation of the Section of Surgery of the Royal Society of Medicine.

**Mr. A. Dickson Wright** (London):

We are collected here on an extremely foggy night to deal with a subject which is to many of us a very foggy one. The pictures of your panel members are in front of us and we welcome this opportunity of discussion.

Chemotherapy at the moment seems to be the greatest hope in the treatment of cancer, and it is interesting that the diseases to which it has been first applied are those that were brought to light by Thomas Hodgkin in his paper published 125 years ago.

I would like to introduce our speakers: On the far right is Professor Haddow, Director of the Chester Beatty Institute, of whom you have already spoken. Next to him is Dr. Wiltshaw who worked for two years with one of your great cancer research workers, William C. Mahoney in Boston. On my left is your friend Dr. Bodley Scott, and on the extreme left Dr. Wilkinson, who is on the staff of the Infirmary at Manchester.

[1]Members of the American panel were attending the American Medical Association's Clinical Meeting in Philadelphia, Pennsylvania. The discussion took place at the suggestion of the American Medical Association. The transatlantic link was provided by courtesy of Messrs. Smith Kline & French Laboratories, Ltd. This account of the discussion is published by kind permission of the American Medical Association.

**Dr. Tocantins:** The first speaker will be Dr. Sidney Farber, Professor of Pathology at the Harvard Medical School.

**Dr. Sidney Farber** (Boston):

In making these introductory remarks I would like to recall that it is less than fourteen years since the temporary control of cancer in man was produced by the use of a chemical agent, thus giving realization to the hope that achievements in the chemical control of infectious disease might be paralleled in cancer. The last few years have witnessed temporary chemical control, characterized by improvement in health, often complete clinical remission, and increase in survival of patients with lymphoma, Hodgkin's disease, and both acute and chronic leukæmias. For many of these great advances we are indebted to our British colleagues, many of them working in association with Professor Haddow at the Chester Beatty Institute.

Under the term chemotherapy we will include alkylating agents such as the nitrogen mustards, antimetabolites such as folic acid and purine antagonists, a group of antibiotics and hormones, hormone analogues, and cortical steroids, and finally viruses, which I would choose to regard as chemical agents when they are effective against cancer, and bacterial products such as the bacterial polysaccharides. A wide variety of disseminated tumours in man, impossible to cure by other methods, has shown response to some of these agents, which have also been of value initially in the treatment of lymphoma and leukæmia.

What of the future? Solution of the problems of acquired resistance and of toxicity would increase greatly the effectiveness of those agents at present in use, and might well convert temporary control into permanent cure. A new era of combined radiotherapy and chemotherapy has been opened. The possibility of treating radio-resistant forms of chronic leukæmia, lymphoma, or Hodgkin's disease by chemical potentiation of radiotherapy is being studied. This study was initiated because of the profound effect of radiotherapy on some hitherto radio-insensitive tumours, such as the rhabdomyosarcoma, when combined with treatment with agents such as Actinomycin D.

Rational approaches to the synthesis of new chemical anti-cancer agents have been created, either by basic research or by knowledge acquired concerning the mechanism of action of carcinolytic agents of proved value. Most programmes are concerned with the synthesis of additional alkylating agents, or with the search for new antimetabolites, anti-enzymes or nucleic acid inhibitors.

These achievements of chemotherapy of cancer in man have led in the United States to the inauguration by Congressional action of the largest voluntary co-operative medical research programme ever attempted in peacetime. This programme, administered by the National Cancer Institute in Bethesda, unites the several private organizations and the branches of the Government with interests in this field, and includes communication with investigators in all countries. Greatly increased support to individual investigators, groups and institutions has been made available for basic as well as applied research. In addition, large co-operative programmes in the several areas of importance such as organic synthesis, screening, methodology, pharmacology, biochemistry, endocrinology, and clinical investigation have made possible rapid expansion in all areas. Of great importance is the large-scale participation of industry in this programme. An empirical programme administered by Dr. Kenneth Endicott of Bethesda is testing during this year over 45,000 chemicals and antibiotics . . . (*BREAK IN TRANSMISSION*) . . . against transplanted tumours in the mouse. Over one hundred clinical groups under Dr. Israel Ravdin of Philadelphia co-operate in a clinical study of chemical compounds in man. It is estimated that at least 4,000 analogues of known hormones have been synthesized by industry, which have not yet been studied clinically. From these various programmes, new antibiotics, hormone analogues, and chemicals will soon become available in considerable numbers, some possibly capable of exerting permanent control of lymphoma, Hodgkin's disease, and acute and chronic leukæmia. Such discoveries in this field would certainly be followed by application to the many other forms of disseminated cancer in man.

**Mr. Dickson Wright:** Dr. Wiltshaw will speak on the subject of when a chemotherapeutic agent can be considered a failure.

**Dr. Eve Wiltshaw** (London):

This apparently negative approach to therapy of malignant disease is presented because of its practical importance to all those people trying out new drugs in clinical practice. It now appears quite certain, not only from what Dr. Farber has said, but also from recent developments at the Chester Beatty Institute that the number of compounds being presented for clinical trial will outpace the material available on which adequate trials can be per-

formed. It is therefore of increasing importance to have some means of deciding at an early date whether it is worth while giving a substance a large-scale trial or not.

The first problem is one of specificity. I believe that Dr. Farber has the feeling that each substance should be tried against every kind of malignancy. This ideal is very difficult to achieve because of the large number of cases needed and the extreme rarity of some forms of tumours. Again, how many cases of each tumour should be given the compound to assess its efficacy, as one can hardly expect 100% success all the time?

The second problem is one of correct dosage. At first an empirical approach must be used to assess its side-effects—if these are serious the clinician feels more inclined to give up a drug early despite the fact that its efficacy may only be manifest when doses producing these effects are given.

If the original nitrogen mustard had been given up because of nausea and vomiting we should never have had the clinical benefit with which we are all familiar to-day. Nowadays, with the newer nitrogen mustards we tend to give them in amounts which do not cause nausea and vomiting.

The third problem is the comparison of one anti-tumour agent against another. The difficulties here are very great because of the variability in the natural history of malignant disease, and the unknown dosage equivalent of two drugs. So far, there are very few papers published comparing two chemotherapeutic agents objectively and this must be a development of the near future.

If a patient with carcinoma of the bronchus and multiple metastases responds to a compound, with regression of the tumour and freedom from symptoms and signs for eight months, then one can be fairly certain the anti-tumour agent is responsible and a great deal more work should be done on it. But if the answer is a negative one after trial on, say, 30 cases of various carcinomata, how far should one press the use of the substance for further trial?

**Dr. Tocantins:** One of the difficulties of the treatment of cancer with chemotherapeutic compounds is to make sure that the result that one obtains is due to the compound used. One begins, of course, with tests in the animals and subsequently applies the results to man. Dr. Sidney Farber said there is now in progress a vast programme of testing these compounds in the human lymphomas and leukæmias, and we have with us here Dr. Emil Frei, the head of the chemotherapy section of the National Cancer Institute who will tell us how to go about this in the right fashion.

**Dr. Emil Frei** (Bethesda, Maryland):

One of the major developments in cancer chemotherapy in the past year or two in the United States has been the establishment of group research, that is the co-operation of several clinical services in the investigation of anti-tumour agents. The orientation of these groups has varied somewhat, though, in general, they are endeavouring to apply the principles of the therapeutic trial which have proved so helpful in drug evaluation in infectious diseases, to cancer chemotherapy. As chairman of one of these chemotherapy groups, I would like to discuss some of the problems of such research.

The major criticism of this approach is that it is premature because the effectiveness of present drugs and potential new drugs is so limited that careful evaluations are unwarranted. In fact we have profoundly effective agents. One has only to observe the virtually complete disappearance of the acute leukæmic process, or the marked suppression of clinical and hormonal evidence of metastatic choriocarcinoma recently described by Dr. Hertz and associates, to appreciate the efficacy of currently used drugs. Such improvement is unfortunately only temporary. Nevertheless such agents certainly deserve careful study as methods of improving response. In this regard, it is important to point out that the marked anti-tumour activity of the folic acid antagonist in choriocarcinoma was achieved with a completely different dose schedule from that conventionally used and was not realized until ten years after these compounds became generally available. It is quite possible that we are far from realizing the maximum benefit achievable with some of our currently used chemotherapeutic agents.

A recurring criticism of the group approach is that, when the ultimate drug arrives for cancer, the question of its efficacy will be answered with a few patients. No elaborate study, no group approach will be required. This is of course true. What it does not say, however, is that the approach to such a drug may well be through the demonstration of a lesser degree of activity in a related compound. A "hole-in-one" is ideal, but infinitely more golf games are won with a putter. The cancer chemotherapist putter is basically the very well-designed—usually comparative—therapeutic trial, and his essential companions on the course are, among others, the statistician and the pharmacologist.

Of the many traps, the major one is the unpredictable natural history of cancer. We recently administered an experimental anti-tumour agent, 6-azauracil, to patients with

advanced, refractory acute leukæmia. 5 of the first 16 patients had some degree of hæmatological improvement. The details of these 5 cases were shown to clinicians both within and outside of our group and opinions ranged in the extreme, that is, everywhere, from the position that we definitely had an active compound, to the opinion that 6-azauracil was inactive. We clearly did not know how much spontaneous improvement may occur in advanced leukæmia nor how long after cessation of anti-metabolite therapy improvement may occur as a result of such therapy. In other words, in spite of a considerable expenditure of time and effort, the question we originally asked ourselves, does azauracil have anti-tumour activity in man, was unanswered. Not only did our driver not make a hole in one, but we are not quite sure in which direction the ball went. The pyrimidine analogues, of which azauracil is one, represent an important potential source of anti-tumour agents. The intensity of investigation in this area would be markedly influenced by an answer to the question, does azauracil or 5-fluorouracil have definite, even if limited, anti-tumour activity for man. For this reason our group is currently involved in a carefully designed comparative study of azauracil; that is, we picked up our precision instrument, the putter.

In summary, the cancer chemotherapy co-operative groups and the approach to chemotherapy that they represent constitute a major advance in methodology. Within a few years the place of chemical agents in the treatment of cancer should be much more clearly defined, and the evaluation of new agents should be at once more efficient, effective, and comprehensive.

**Dr. Tocantins:** There are many pitfalls in the evaluation of these compounds, and that may account for the slowness of the development of knowledge in this field.

**Professor Alexander Haddow** (London):

Dr. Frei has spoken of the design and execution of therapeutic trials. I would like to spend a few moments in considering design and execution in the experimental chemotherapy of animal tumours. The design of experiment is partly empirical and partly rational. On the empirical side, we are always curious to know the effects of all kinds of chemical agents on tumours, but in this country we are perhaps less enamoured than in yours of purely routine screening. I believe that the design of experiments must be flexible and selective in order to establish leads which can then be pursued more systematically. On the rational side we have had many leads from the study of experimental carcinogenesis. One example I might quote is the discovery of the carcinogenic action of the amino stilbenes, which, in part, led on many years later to the discovery of potential chemotherapeutic activity in the somewhat related styryl quinolines. Again on the rational side, I plead for the importance of a working hypothesis, no matter how faulty. One good example is the cross-linking hypothesis originally devised to explain the requirements for action in the alkylating agents, later shown to be unduly simplified, but nevertheless one which has proved tremendously fruitful in practice in leading to the discovery of new types of active agent. In other words I believe strongly that experimental chemotherapy should not be divorced from the fundamental programme. Each reacts on the others essentially.

As to execution, certainly it is desirable to test compounds on as wide a spectrum of tumours as is possible. But in practice this is not always easy and again it is necessary to be selective. In my own Institute many years ago we selected the Walker rat carcinoma among many others as a desirable initial test object for orientation purposes. It is not so sensitive as to be misleading, nor is it so resistant that it may hide the action of potentially interesting substances. Its use has set us on the trail of many leads, some of which have led to successful clinical application. Several agents are now known which will suppress the growth of this tumour completely. Compounds showing promising activity are then subjected to more strenuous tests: for example, on the growth of other transplantable tumours, spontaneous mammary cancer of mice and chemically induced sarcomata. In general these tend to be much more resistant. The small number of agents which still show some promise may be considered for clinical trial.

This brings me to the point of the extent to which the findings from animal experiment can be translated to man. Of course we know many which cannot be translated on account of undue toxicity and side-effects, the reason perhaps depending on differences in metabolism of these substances in different species. Nevertheless we have been impressed by the frequency with which animal findings can be applied direct to man, and good examples are seen in chlorambucil and Myleran. Clinical trial should be started with the utmost caution and subject throughout to the very highest critical standards. It may take a year or two to establish the details of dosage and the general pharmacology. When this is done, and prior to publication, we found great advantage in extending the trial to other centres. In conclusion, I would like to record our thanks to very many American friends who have done so much to help us in this direction, and especially to Dr. Sidney Farber.

**Mr. Dickson Wright:** I would like now to pass over to Dr. Tocantins for him to introduce his third speaker, Dr. Custer, who is going to speak on the relation of the histology of lymphoma and leukæmia to the aggressiveness of the process and its response to therapy.

**Dr. Tocantins:** Dr. Philip Custer, who is Associate Professor of Pathology at the University of Pennsylvania School of Medicine, has given a great deal of thought to the study of this particular point and he is now going to tell us his experience with it.

**Dr. Philip Custer** (Philadelphia):

As Dr. Frei has already emphasized, the natural behaviour of a given type of malignant tumour in a given individual is quite unpredictable. In no category of neoplastic disease does this hold so true as in the lymphoma-leukæmia complex, where even the untreated tumour may display vagaries including changes in its cellular composition.

It is traditional that the lymphomas and leukæmias are divisible by virtue of their predominant histologic structure, and various schemes of terminology have been applied, each with its merits and demerits. In this country the more usual catalogue of lymphomas designates the follicular or nodular form, the lymphocytic or lymphosarcomatous type, the reticulum cell or pleomorphic variety, and Hodgkin's disease, the last being subdivided into the so-called paragranuloma in which lymphocytes predominate, the granuloma with its multiplicity of cell types and inflammatory, necrotizing and desmoplastic aspects, and the sarcoma which resembles primary reticulum cell lymphoma. British pathologists seem to prefer the term "reticulosis" with appropriate adjectives to indicate this variety of patterns except for Hodgkin's disease, under which our subdivisions are unspecified. Leukæmias are classified as granulocytic, lymphocytic, monocytic, thrombocytic and plasmocytic, with gradients in differentiation of the cells which generally signify an acute or chronic course. Relationships with erythremia, erythremic myelosis, myeloma and myelofibrosis occasionally become apparent.

It is becoming accepted, however, that the cellular pattern of the lymphomas and leukæmias is not necessarily a static one, that transitions from one form to another do come about, and that a composite tumour made up of various derivatives of the reticulo-endothelial system, including fibroblasts and angioblasts, may evolve from an initially pure form of neoplastic cell growth.

As to the clinical manifestations of the malignant process in each category, whether pure, merging or mixed, we have found it quite impossible to predict the course of the disease, irrespective of treatment. Left to itself, the growth may pursue an indolent course for some years, perhaps with completely static periods or even spontaneous regressions, as one notes most frequently with follicular lymphoma, Hodgkin's paragranuloma, and chronic lymphocytic and granulocytic leukæmia. Yet at some unpredictable time any one of these relatively benign processes may explode into a rapidly fatal phase. In a comparable group of patients in whom the microscopic appearances of the malignant tissue are identical, however, there may be an extremely aggressive growth surge almost from the very outset.

This capricious behaviour likewise applies to the responsiveness of these tumours to treatment. Malignant tissue in one person may melt away almost miraculously following administration of a few milligrams of nitrogen mustard or one of its analogues, but a histologically identical tumour in the next patient may remain relatively untouched by the same agent in like dosage. Furthermore, a lymphoma quickly destroyed by a cancerocidal compound may return to plague the patient in a few weeks, while the same spectacular disappearance of precisely the same type of tumour in another person may be long-lasting. Again, an initially stubborn tumour which requires repeated treatment of one sort or another at the outset may recede and remain quiescent for years without further concern.

Individual sensitivity to the administration of cancerocidal agents is not confined to neoplastic tissue. There is a rather wide scatter in the amount of these drugs that patients can tolerate before bringing about serious depression of the bone-marrow and consequent cytopenias in the peripheral blood. All too often the enthusiastic chemotherapist will destroy the patient along with the malignant disease by virtue of an empty bone-marrow. It is of extreme importance, then, that every patient be regarded as an individual experiment in connexion with the administration of any cancerocidal agent, be it conventional or new.

All of this points to the human as the poorest of experimental animals, particularly the sick human, who is in no sense comparable to highly inbred strains of tumour-bearing animals on whom the new chemotherapeutic materials are tried initially. Thus, the first clinical trial of a substance which has shown promise in animal experimentation may prove very discouraging, for it must be used with patients who have failed to respond to conventional treatment. While most of them die, the study of their tissues at autopsy none the less offers an important means of evaluating the relative toxicity of the chemical on both

neoplastic and normal cells, especially the blood-forming ones which are generally the most sensitive. The final phase, and the one requiring the greatest courage on the part of the investigator, is the testing of a promising cancerocidal agent on patients whose malignant disease is not overwhelming and who could probably be salvaged by conventional forms of treatment. Here, too, one is handicapped in his evaluation by the individual variants already recounted.

In an effort toward better understanding of the variables in humans, we have planned experiments which might disclose differences in host resistance to the tumour or in antigenic capacity of tumour tissue. By some such means it might prove possible to weight the results of clinical chemotherapy of cancer.

**Dr. R. Bodley Scott** (London):

I would like to continue the theme which Dr. Custer has started. I think that in this connexion it is important to divide lymphomas from leukæmias because there is a considerable difference between the two in the relation between histological appearances and response to treatment and the aggressiveness of the tumour. So far as the lymphomas are concerned, there is remarkably little correlation between the histological picture and the aggressiveness of the disease.

Dr. Custer's remarks also open up the complicated question of the classification of these diseases, and this is as confused as was the classification of nephritis twenty-five years ago. Dr. Custer has offered a classification which probably would not be acceptable to most clinicians or pathologists in this country. Many of us do not believe in three different kinds of Hodgkin's disease, one of which may turn into the other; we believe that the histological pattern remains essentially constant, and that one disease does not turn into another in the way that has been recorded. If these different histological patterns indicate different diseases, do they show a different response to different chemotherapeutic agents? The answer so far as the lymphomas are concerned is yes. For example, most people would agree that the original nitrogen mustard, $HN_2$, is much more effective in Hodgkin's disease than are other drugs such as chlorambucil or the polyethyleneimines. On the other hand it is the usual experience that chlorambucil and the polyethyleneimines are more effective in the diseases in which the main feature is lymphoid hyperplasia—lymphatic leukæmia, lymphosarcoma, and lymphoid follicular reticulosis or follicular lymphoblastoma. It may be that the original nitrogen mustard is more effective against reticulum cell proliferation, and the other drugs against lymphoid cell proliferation.

When it comes to leukæmia, it seems to me that the situation is a good deal clearer. There is undoubtedly a relationship between cytology and aggressiveness in chronic myeloid leukæmia. For instance, at one extreme there is the rare neutrophil leukæmia which goes smouldering on for perhaps ten years; in the middle there is the common chronic myeloid leukæmia in which the average duration is perhaps three or four years, and this will usually terminate by a sudden outpouring of primitive myeloblasts.

There is also a clear-cut relationship between the response of the diseases to chemotherapeutic agents. For instance, chronic myeloid leukæmia will respond by some degree of remission to almost all chemotherapeutic agents, but when it reaches the undifferentiated myeloblastic stage it only responds to 6-mercaptopurine. In chronic lymphatic leukæmia, the small cell type is generally admitted to run a more chronic course than the large cell type, although there are many exceptions. Finally in the acute leukæmias there is possibly some relation between cytological type and the response to chemotherapeutic agents. When there is general agreement that a case is one of myeloblastic or lymphoblastic leukæmia, there is a good chance that remission will occur with 6-mercaptopurine. Remission is much less likely when it is one of those cases where nobody can agree on the exact nature of the cell and when one hæmatologist says it is a myeloblast, the next a lymphoblast, and the third a monoblast. That is to say, where the cells are completely undifferentiated, the chances of remission are far less good.

**Dr. Tocantins:** We must look for the answer to the rationale of chemotherapy, principally to the man who is doing fundamental experimental work. We have with us here this afternoon one of the leading exponents, Dr. Howard Skipper, who is Director of the Southern Research Institute and Professor of Experimental Pathology, University of Alabama Medical School

**Dr. Howard Skipper** (Birmingham, Alabama):

As a Southerner, I am particularly honoured to be asked to join this transatlantic conference. As our friends in England may remember, there was a bit of a strife in this country between the North and the South almost a century ago. We, in the South, did not really lose this war; we simply wore ourselves out winning battles. This conference is an excellent demonstration of the absence of provincialism or nationalism in medical science.

I was asked to discuss a topic on which there is no general agreement, no hard core of

accepted facts—just opinions and the belief that if there were at hand *a sound rationale* for direction of research in the area of cancer chemotherapy, the whole world-wide effort would proceed in a more orderly, efficient, and rapid manner. Therefore, in the absence of any real over-all rationale for cancer chemotherapy, you must listen to some vague "semi-rationales", or something allied thereto.

The biologic entities most generally associated with the cellular change resulting in cancer are genes and viruses. We know that both genes and viruses are nucleoprotein in nature and that the hereditary capacity of genes and viruses is contained in their nucleic acids. Thus, on a biochemical basis, cancer might appear to be a lesion in cellular nucleoprotein possibly resulting in a deleted or inactivated anabolic or catabolic enzyme responsible for some rate-controlling biochemical events. Here I have covered, or attempted to cover, a considerable ignorance with big words, but I have also tried to suggest a general concept which would allow some correlation between the somatic mutation and virus ætiology concepts (a virus-like particle is structurally well suited to causing genic changes in a cell). Also the concept that gene changes are associated with cancer is well suited to the enzyme-deletion concept which appeals to me. From the theoretical standpoint, it seems possible that rates of normal cell growth and division may be associated with a balance between certain anabolic and catabolic reactions, and deletion of catabolic catalysts (resulting from gene changes) might well shift the balance to a state of uncontrolled net synthesis and cell growth and division.

The agents which affect the course of leukæmia in animals and man, by and large, are agents which affect nucleotide and nucleic acid metabolism. X-radiation, a long-employed method for treatment of certain leukæmias and many other neoplasms, is an inhibitor of nucleic acid synthesis. Urethane, an antileukæmic agent discovered by Professor Haddow and his associates, affects glutamine and pyrimidine metabolism. Azaserine and DON, glutamine antagonists discovered by the Sloan-Kettering and the Parke, Davis groups, are inhibitors of purine nucleotide synthesis. A-methopterin, a useful temporary anti-leukæmic agent discovered by Dr. Farber and his group, blocks purine nucleotide and nucleic acid thymine synthesis. 6-mercaptopurine which came from collaborative work between the Burroughs Wellcome and Sloan-Kettering Institute laboratories and which causes temporary regressions in some cases of human leukæmia, is almost certainly a purine nucleotide antagonist. Work in both Professor Haddow's laboratory and ours has shown that nitrogen mustards do indeed alkylate nucleic acids.

Thus, generally speaking, it appears that the antileukæmic agents in use to-day probably act as inhibitors of nucleotide metabolism (affecting co-factor or nucleic acid synthesis) and, in turn, inhibit cell division. Therefore, one rational approach to cancer chemotherapy might be synthesis of a wide variety of analogues of the cellular intermediates *en route* to co-factor nucleic acid moieties. I can think of a great number of compounds that could be synthesized for trial on this semi-rational basis. Many of these, I am certain, are being made to-day in laboratories throughout the world.

A second and perhaps more long-term rational approach is the direct search for the biochemical lesions responsible for cancer. If I were in possession of a genie with the power to grant one wish, I would, of course, ask the structure of a compound which would cure all cancer in man, but if this genie was a specialist who did not go along with applied research (a real fundamental genie who gave answers only to fundamental questions), then I would ask him what are the exact basic biochemical changes responsible for alteration of a normal cell to a cancer cell. I would publish this knowledge immediately (giving proper credit) and hope that such knowledge would make possible a direct scientific approach to the problem of (1) action which might be taken to prevent such chemical events in man, or (2) the design of drugs which would exploit these biochemical differences and provide the cytotoxic specificity required for curative cancer chemotherapeutic agents.

Still another rational approach to advancement of the status of cancer chemotherapy is that of unravelling the cause of failure of our presently known temporary antileukæmic agents. Development of drug-resistant population of neoplastic cells is possibly one stumbling block *en route* to our goal. The basic knowledge required for some understanding and rational planning on the problem of drug resistance is being acquired more rapidly than many of us realize. It may be hoped that the possession of such knowledge will make it possible to devise means for coping with the development of drug resistance associated with present clinical chemotherapy of the leukæmias.

Finally, there are two general rational approaches to the advancement of cancer chemotherapy: (1) a search for the basic lesion of neoplasia on the biochemical level with hopes that such knowledge will allow for selection or design of drugs with greater usefulness, and (2) continued design and trial of drugs on the best hypotheses at hand hoping that better drugs will turn up and that study of their modes of selective action will lead us to the basic biochemical lesions of cancer. I personally encourage and endorse efforts in both directions.

**Dr. Tocantins:** The study of drug resistance and of the mechanism of action of the chemotherapy of leukæmias and lymphomas leads almost into the heart of the mechanism of life. In attempting to control cancer we are going to learn a great deal about the mechanisms of life itself, underlining Dr. Ewing's statement that the study of cancer was virtually the study of life.

**Mr. Dickson Wright:** Professor Haddow will now speak upon the prospects of cancer chemotherapy.

**Professor Haddow:**

Cancer chemotherapy is obviously still in an embryonic stage. Nevertheless a good deal of progress has been made in the past ten years, resulting in agents which are clinically useful, even if only in a very limited sense. This progress still continues with experimental emphasis on agents with a far higher therapeutic index than those so far used. The present lines of work must be extended, and it would be quite wrong to discount the possibility of discovering new agents of greatly enhanced activity and wider application. But having said this, I am doubtful whether purely cytostatic agents or the antimetabolites, as we know them, have any permanent place in treatment. I have already made the point that the study of experimental chemotherapy should not be divorced from fundamental studies, and I believe the main importance of all these agents lies not in their practical application but in the light they shed on mechanisms of action, and on the nature of the cancer cell itself. As one example, many of the alkylating agents are capable of carcinogenic action in animals and much has been learned of the ways in which they could combine in the cell, with nucleoprotein perhaps in particular, to bring this about. The tentative conclusion, although not by any means proved, is that such agents bring about malignant change through a process of cytogenetical loss. The biochemical nature of the loss is not so far known. We have, however, speculated along the lines just referred to by Dr. Skipper whether it might involve the elimination of enzyme systems responsible for regulating the growth of the normal cell, so liberating the synthesis of growth-promoting substrates. This would account for the continuous and unregulated growth of the cancer cell. This idea is not only attractive but in very many ways reasonable. If it were to prove sound, we might perhaps envisage a new kind of chemotherapy in the future, in which the growth-regulatory functions, apparently deficient in the cancer cell, would be re-imposed. This recalls certain types of substitution-therapy we already employ elsewhere, especially in pernicious anæmia, much of the underlying pathology of which is reminiscent of certain aspects of malignant change.

To summarize, progress will be made on present lines, we never know with what surprises, but the same agents will also be used to study the mechanism of carcinogenesis and to establish the essential biochemical differences between normal and cancer cells. This could lead to a new form of chemotherapy based upon rational understanding, and very different in kind from that which we employ to-day.

**Dr. Tocantins:** We are very fortunate this afternoon in having two of the leading exponents of the chemotherapy of leukæmia in this country, Dr. Farber and Dr. Burchenal. Both of these men have made very vigorous attacks on the leukæmia problem, and I take great pleasure in introducing Dr. Joseph Burchenal, Professor of Medicine, Cornell University Medical College, who will speak on the practical clinical results that can be obtained by chemotherapy of the leukæmias.

**Dr. Joseph Burchenal** (New York):

There are three classes of agents at present available for the treatment of acute leukæmia. First there are the folic acid antagonists discovered by Dr. Farber's group, of which Methotrexate, previously called amethopterin, is perhaps the best. Secondly, there are the purine antagonists exemplified by mercaptopurine, chloropurine and thioguanine. None of the latter is any better than 6-mercaptopurine. Thirdly we have the adrenal steroids. Of the last the prednisone type is preferable since there are less of the undesirable side-effects of sodium and water retention. The folic acid antagonists and purine antagonists require three to eight weeks to exert their beneficial effects, but the remissions are generally longer than with the more rapidly acting steroids. For that reason we believe that the folic acid antagonists and the purine antagonists should be the main chemotherapeutic agents, and that the steroids should be reserved for emergency situations such as fulminating disease or gross hæmorrhagic tendency, where rapid action is essential, or for cases in which resistance to the antimetabolites has developed. In the acute leukæmias, signs and symptoms of meningeal infiltration occasionally develop. This may be treated successfully by intrathecal injections of Methotrexate or by radiation to the whole cranium. Beneficial effects have been achieved by intrathecal Methotrexate both in patients whose peripheral disease was resistant as well as in those whose disease was sensitive to Methotrexate.

Acute leukæmia in children may respond to all three types of therapy and a high percentage of patients will respond to at least one.

With such a regime as I have outlined we have found 50% of our last 253 children with acute leukæmia survived for just over twelve months as compared with the usual 50% survival of four to five months before these specific modes of therapy were available. Previously untreated adults rarely respond to the folic acid antagonist, but about 15–25% will respond to the purine antagonist and about the same response may be expected from the steroids. In patients who have responded at first to 6-mercaptopurine and have then developed resistance, Ellison showed that there is a 30% remission rate with Methotrexate so that it is important not to abandon folic acid antagonists in the acute leukæmias of adults. They should be tried after mercaptopurine has been tried. Since the percentage of adults responding to any therapy is small, the overall increase in survival time is not very significant, but in those in whom remissions are achieved, a median survival time of about twelve months can be expected.

In chronic granulocytic leukæmia, Myleran is the chemotherapeutic agent of choice. How survivals will compare over a long term with those after X-ray therapy is impossible to state for certain at this time. Preliminary studies by Krakoff *et al.* suggest that chlorambucil will also produce remissions in this disease.

In chronic lymphocytic leukæmia, chlorambucil is the drug of choice, but X-ray therapy to nodes and spleen is also excellent treatment. Preliminary studies by Galton and by our group have shown that Myleran can also produce remissions in this disease, but how it will compare with chlorambucil cannot at present be stated.

The adrenal steroids are of considerable value in controlling the hæmolytic anæmia and thrombocytopenia associated with this form of leukæmia, but again it is too early to assess the effects on survival time.

In the localized lymphomas we prefer localized radiation therapy. When the process is generalized, chemotherapy is indicated. For rapid effect in Hodgkin's disease, we prefer intravenous nitrogen mustard, or possibly intravenous T.E.M. (triethanomelamine). For maintenance therapy chlorambucil by mouth seems to be well tolerated and well absorbed. The adrenal steroids will produce regressions in lymphosarcoma and reticulum cell sarcoma, and are frequently beneficial in treating the hæmolytic anæmias associated occasionally with all the lymphomas.

The effects of these forms of therapy on the overall median survival time of patients with lymphomas is not at present clear, but it is our clinical impression that in certain cases marked increase in expected survival time can be achieved.

**Mr. Dickson Wright:** Dr. John Wilkinson will speak on practical clinical results.

**Dr. John F. Wilkinson** (Manchester):

I propose selecting from my series of 900 cases of leukæmia that I have treated with chemotherapeutic agents since 1942 when I first introduced the trichlorethylamine hydrochloride for intravenous use. I am interested that a number of speakers are coming round to my view that the most effective preparation in many of the chronic leukæmias is intravenous trichlorethylamine hydrochloride, and that the newer preparations are not so good although perhaps a little more gentle with the patients in that they do not produce as much nausea.

In the acute leukæmias there are very few agents that can produce prolonged and beneficial effects. With the nucleotoxic agents and the antimetabolites that previous speakers have mentioned such as aminopterin, amethopterin and 6-mercaptopurine, we have only been getting approximately 30% remissions for periods up to twelve to eighteen months. It is easy to get toxic effects if you are not careful, and the subsequent relapses are not easy to treat.

Our best results have been obtained with the steroid hormones, particularly prednisolone, and by giving prednisolone in high dosage and for prolonged periods we do get approximately 40% remissions for much longer periods. The first patient I treated was in 1951, and she only required treatment for six months. She had two courses of treatment in that period, and for six years has been perfectly fit and well without any symptoms. The blood is normal, the marrow is normal. Clinically she is a perfectly well child, back at school and leading a normal life.

We have tended to give up the anti-folic acid agents and concentrate on the steroids. It is interesting that children respond much better than adults in these acute leukæmias with one exception—the acute monocytic leukæmias appear to respond better in adults, some of whom we have been able to keep going for one to two years.

The chronic leukæmias do not benefit from the steroids nor from the antimetabolites, except that a few chronic myeloid leukæmias may respond to mercaptopurine. Both chronic myeloid and chronic lymphatic leukæmias respond extremely well and rapidly to intravenous trichlorethylamine hydrochloride. It may only be necessary to give two or three doses of 5–6 mg. intravenously, and large glands, the spleen and the liver will go down in a matter of a week or a fortnight. Of a series of 140 severe cases selected because they had large glands, spleens and livers, in the course of one to four weeks 94% lost their splenomegaly, and 91% their enlarged glands, the white cells returning to normal. They needed subsequent similar short courses of treatment at intervals varying from three months to over two years. One or two of these patients whom I first treated during the war are still alive.

The chemotherapeutic agents that we give orally have also introduced interesting possibilities. Chronic myeloid leukæmia responds very well to Myleran. One can ultimately reduce the dose in many cases to 2 mg. once a week, and with perhaps an occasional slight increase. Colcemid, (deacetyl-methyl-colchicine) acts similarly, but is not quite so easy to control. Chlorambucil has been disappointing in the myeloid leukæmias.

T.E.M. is a very dangerous drug, and, although it may be efficient for a short time, aplastic anæmia, thrombocytopenia, and agranulocytosis are frequent complications. I think T.E.M. should be removed from our armamentarium, particularly as we have better and safer therapeutic agents.

The chronic lymphatic leukæmias do not usually respond to Myleran, Colcemid, T.E.M., and Urethane, but they may respond to chlorambucil or to the substance R 48. If the patient has suitable veins the quickest and best treatment is either intravenous nitrogen mustard or intramuscular thioTEPA. Hodgkin's disease reacts similarly, and I know of no treatment as good as intravenous trichlorethylamine hydrochloride given in small dosages. In 80 cases of Hodgkin's disease, all selected because they had large glands that could be photographed and with large spleens, with doses of 6–30 mg. spread over two to three days, there was complete regression of the splenomegaly in 76% and partial regression in 16%, whereas in the lymphadenopathies 83% lost their large spleens and 9% showed regression. The survival time of these patients has been good, the longest to date being twelve years. None of these cases were of the mild type that often does not need treatment. In the other reticulosis, the results are not so good.

**Dr. Tocantins:** I regret that we are running a little behind our time because much of what Dr. Wilkinson said would I am sure be challenged by certain members of our panel. I would like to state that these proceedings are being broadcast and are being heard now in the National Cancer Institute in Bethesda, Maryland, and at the Walter Reed Army Medical Centre. We are even getting questions relayed to us from these two audiences.

The next few minutes will be dedicated to the questions from our panel to the British panel. The first question, which is being asked from Dr. Burchenal, is directed to Dr. Bodley Scott. Have you any experience with chlorambucil in the treatment of chronic granulocytic leukæmia or Myleran in chronic lymphocytic leukæmia?

**Dr. Bodley Scott:**

I have had no experience but I would suggest that the question be referred to Dr. Wiltshaw who I believe has some experience of Myleran in treating chronic lymphocytic leukæmia.

**Dr. Wiltshaw:**

Dr. Galton has treated 3 cases of chronic lymphatic leukæmia with Myleran, and he felt that in these cases he got a definite drop in the white cell count, and a response which could be expected with any of the other drugs, the only disturbing feature was that one of the cases got what he thought was disproportionate platelet drop and one case developed purpura. Of these cases, 2 of them were treated with 4 to 6 mg. daily and 1 case was treated in the early days of Myleran with large doses, in five days she received 318 mg. This patient had no purpura and proceeded to a remission of about two years. We think it worth while to use this drug in chronic lymphatic leukæmia.

**Mr. Dickson Wright:** Professor Haddow has given me a question for Dr. Frei. "Is there any evidence for the effectiveness of chemotherapy in delaying or preventing metastasis?"

**Dr. Frei:**

In choriocarcinoma, all of the patients treated had extensive metastases. There are studies currently in progress to determine whether chemotherapeutic agents, particularly alkylating agents, given at the time of surgery for the primary lesion, will prevent the subsequent development of metastases.

**Dr. Tocantins:** I would like Dr. Farber to answer some of the points that were brought up by Dr. Wilkinson, especially the giving up of folic acid antagonists in the treatment of leukæmia. Dr. Farber is the leading exponent of this treatment.

**Dr. Farber:**

May I combine my answer with the question of survival in some 900 children with acute leukæmia treated with folic acid antagonist, 6-mercaptopurine, and the corticosteroids during the past eleven years.

We have 50% survival fourteen months after the beginning of treatment; this includes all children whether they died within an hour after admission, or whether they had treatment or not. 10% are still alive at two and a half years; a few are still alive at four to four and a half years. One child had an unbroken folic acid antagonist remission of eighty-eight months—seven years and four months—and died, I am unhappy to say, a few weeks ago with staphylococcus infection, ninety-eight months after the beginning of therapy. It is not a question of which one of these agents is the best. In the course of treatment we need every one of them, and there is no question from our experience that folic acid antagonists may be given safely without the production of toxic effects and be productive of very long remissions. This is also the experience of Dr. Burchenal and many other people in this country. So that answer to the question is that all four of these agents, the corticosteroids, ACTH, folic acid antagonists and purine antagonists, have a very important place in the course of treatment of any given patient with acute leukæmia.

**Dr. Tocantins:** We have a question from Dr. Farber directed to Professor Haddow. "Do you consider it worth while to fashion experimental chemotherapy against lymphoma and leukæmia on the assumption that these disorders may be caused by a transmissible virus or agent?"

**Professor Haddow:**

I think your question indicates what I have already tried to stress, namely the great importance of fundamental studies on causation, including causation by viruses, and I think it is from these that new leads in chemotherapy will probably come. But I doubt if we are yet in any position to fashion agents against lymphoma or leukæmia on the assumption that these may be caused by some transmissible substance.

**Mr. Dickson Wright:** I would like to direct a question to Dr. Philip Custer from Dr. Wiltshaw, "What is the most effective agent in the treatment of myelomatosis?"

**Dr. Custer:**

So far Urethane has been our anchor to windward with myelomatosis. We have obtained good palliation in an appreciable number of patients. The majority, however, have not had any great prolongation of life, with the exception of one patient who is now in her fifth year of the disease under constant Urethane control.

**Dr. Tocantins:** I have a question from Dr. Farber to Dr. Bodley Scott. "What are your expectations in the treatment of the lymphomas from still greater super-voltage radiotherapy?"

**Dr. Bodley Scott:**

What one should expect from super-voltage radiotherapy is perhaps that a greater dose can be given to tumours, particularly deep tumours, with less damage to the skin and to the surrounding tissues. Therefore super-voltage therapy has a limited usefulness in lymphomata, particularly where the main mass is in the mediastinum or in the vertebral column causing pressure on the cord. Radiotherapy is never more than symptomatic in the treatment of these diseases because the diseases are potentially generalized from the beginning. I do not believe we can expect very much more from greater super-voltage radiotherapy than we already have from present super-voltage radiotherapy.

**Mr. Dickson Wright:** I would like to ask a question from Dr. Wiltshaw to Dr. Frei. "What is the place of chemotherapy in the treatment of the lipoid storage diseases?"

**Dr. Frei:**

That is a difficult question. The lipoid storage diseases in many respects resemble primary proliferative disorders. For this reason various anti-tumour agents have been administered to such patients. Evaluation is difficult because the natural history and interrelationships of some of these diseases are poorly defined. I know of no clear evidence that chemotherapy is beneficial in the lipoid storage diseases with the exception of hypersplenism which, of course, can develop and complicate any variety of lipoid storage disease. Under these circumstances adrenocortical steroids or ACTH are frequently helpful.

**Dr. Tocantins:** I have a question here which was sent from the National Institute of Health directed to Dr. Burchenal. "What is the best dosage schedule for Methotrexate in acute leukæmia?"

**Dr. Burchenal:**

I am not sure that anyone knows the best dosage. Not nearly enough work has been done clinically with differing dose regimes. The dose we generally use in a child, say of 5 years of age or slightly under, is 2½ mg. once a day by mouth. If that produces no effect after a time it may be necessary to go to 5 mg. daily, with the 2½ mg. daily we rarely see toxic manifestations and we can usually get remissions without toxicity.

**Mr. Dickson Wright:** A question from Dr. Bodley Scott to Dr. Skipper. "Is combined therapy by a number of agents at once of value?"

**Dr. Skipper:**

I can only speak of the effect of combination chemotherapy in experimental animals. I should like to make one brief statement on that point and then pass to Dr. Burchenal who has carried out combination chemotherapy in the clinic. I think that this is a theoretically very promising approach to the advancement of the status of cancer chemotherapy for two reasons. Theoretically, it is a good means for preventing the development of drug resistance, and also a method for obtaining sequential blockade in a series of chemical events which might result in potentiation. Certainly, unequivocal potentiation of the antileukæmic activity of drugs has been observed with combinations of drugs in experimental leukæmias and tumours.

**Dr. Burchenal:**

6-mercaptopurine and azaserine in mouse leukæmia and in sarcoma 180 have a definite potentiating effect. For that reason the combination of 6-mercaptopurine and azaserine has been tried in children with acute leukæmia. This study has been done by some 14 different co-operating groups and is still in progress. It appears that in a small percentage of patients the length of remission on 6-mercaptopurine can be prolonged by the addition of azaserine. I think that combination chemotherapy has a great future. All we need are some good compounds to use in combination.

**Dr. Tocantins:** We now have only about a minute or so to go, and there is one basic question that Dr. Skipper would like to direct to Professor Haddow. "Is enough effort being directed towards the discovery of biochemical differences between normal and neoplastic cells?"

**Professor Haddow:**

I think that insufficient work is being done along these lines. But much more has been done during the past ten years than ever before. Of all the rational approaches, this is by far the most important, and in saying this I am thinking not only of biochemical differences but also of biophysical and immunological differences between normal and cancer cells.

**Dr. Tocantins:** I should like to say how much pleasure we have had in this conversation with our British colleagues, and I am sure that for most of us here it has been very educational to hear what is thought on these matters overseas. What has struck us particularly is the agreement that exists between us. There have been disagreements, of course, and those could be probably exploited a little more, but what impressed me is the amount of agreement. I should like to convey to our British colleagues and to the co-ordinators our thanks for making this interchange possible.

**Mr. Dickson Wright:** Goodbye Dr. Tocantins and your colleagues, and thank you very much for the really splendid way you have covered the subject. I have written down here 26 different chemotherapeutic agents that have been mentioned during the course of this discussion and 12 different diseases. That gives an impression of the complexity of the subject, but I feel we have all gained a great deal from it and we are very grateful to Messrs. Smith Kline and French Laboratories, Ltd. for making this possible.

# Section of Dermatology

President—JOHN T. INGRAM, M.D., F.R.C.P.

[*January* 16, 1958]

**Psoriasis.**—D. I. WILLIAMS, F.R.C.P.

D. S., aged 41, housewife.

*History.*—This patient has suffered from psoriasis since the age of 5 years. For most of the time it has not been severe and has been readily controlled by treatment although never completely removed. At its best the lesions are confined to the legs only. In January 1957, she had influenza followed by a generalized flare of the psoriasis. She attended King's College Hospital for the first time at the end of March when she was suffering from a generalized scaling eruption, considerable pigmentation and pallor. The nails were thickened and discoloured. The lymph glands in the axillæ were enlarged. As she refused admission to hospital she was treated as an outpatient, with very limited success.

In July 1957 she consented to come into hospital on account of the generalized psoriatic erythroderma. At that time no other clinical abnormality was found. She was treated with prednisone, 15 mg. t.d.s. with some improvement. Reduction of the dose of this drug to 5 mg. t.d.s. was followed by relapse. For domestic reasons she left hospital early in October with the condition still extremely unsatisfactory. Further outpatient treatment did nothing to restore the condition. She was readmitted in the middle of November, still with an exfoliative erythroderma and generalized pigmentation with a suggestion of reticulation of the pigmentation, particularly around the neck. This time the liver was felt to be enlarged, three fingerbreadths below the costal margin. At the end of a month she had developed large numbers of macerated hyperkeratotic papules on the wrists and on the lower third of the legs. She left hospital just before Christmas and continues to attend as an outpatient.

*Past history.*—Non-contributory.

*Family history.*—No psoriasis.

*On examination.*—Generalized pigmentation, reticulate around the neck, with some telangiectasia. The trunk and limbs are covered with aggregates of dusky, small, slightly scaly papules, leaving tiny islands of apparently normal skin. There is considerable scaling of the lower third of the legs; the nails are thickened, discoloured and distorted. The liver is palpable three fingerbreadths below the costal margin. There is axillary adenopathy.

*Investigations.*—Biopsy of skin (2.12.57): "Section shows some hyperkeratosis and parakeratosis. There is a moderate acanthosis with elongation of the rete pegs. The papillæ are correspondingly elongated with a slight tendency towards clubbing at their apices. The upper part of the corium is diffusely infiltrated by a mixed cellular inflammatory exudate consisting of numerous reticulo-endothelial cells, and moderate numbers of lymphocytes and polymorphonuclear leucocytes. The histological picture is that of psoriasis." (Dr. M. E. A. Powell.)

White cell count persistently normal. Hæmoglobin 70–84%. Electrophoretic pattern: no significant change. Blood urea, serum proteins, liver function tests and chest X-ray were all normal.

*Comment.*—Members are probably wondering why I labelled this case "psoriasis". If I had not called it "psoriasis" I think I should have got lost in a vast waste of dermatological terminology. Certainly I was told she had had psoriasis since the age of 5 and one could suspect on looking at her, particularly at her arms, that there are remnants of psoriasis but at the time I saw her the condition had changed considerably and I felt that something nasty was happening. By the time I saw her she had pigmented considerably, there was a suggestion of reticulation and perhaps a little telangiectasia. I do not think there was any real atrophy and since that time she has developed all over the trunk a large number of dusky papules of a rather violaceous tint. The liver is now easily palpable, I do not know whether this is significant; so many people with exfoliative dermatitis get large livers. My feeling is

that this woman will ultimately develop one or other of the reticuloses. I thought it was interesting in view of the discussion we had last year concerning psoriasis, and the possible development of mycosis fungoides (*Proc. R. Soc. Med*, **50**, 771, 931). A few weeks ago Professor Degos told me of a number of cases of psoriasis at the St. Louis Hospital in Paris which had developed mycosis fungoides.

**Dr. A. Jarrett:** I thought this was a case of psoriasis that had developed into an exfoliative erythrodermia. I agree with Dr. Williams that the enlarged lymph glands would probably show the histological features of lipomelanic reticulosis, but I do not think that she will inevitably progress to a malignant reticulosis; in fact I think the chances are she will not. In a series of 16 cases of lipomelanic reticulosis followed over several years (3 of them to autopsy), none developed a malignant reticulosis.

**Dr. I. B. Sneddon:** I recall a case which was thought to be psoriasis for ten years and which then developed exfoliative dermatitis. After eighteen months in hospital small doses of superficial X-ray therapy entirely cleared the exfoliative dermatitis. A year later, typical tumours of mycosis fungoides appeared and the disease ended fatally. I agree with Dr. Williams that such a course may happen here.

**Dr. F. F. Hellier:** One has seen cases before in which a dermatosis which has been apparently psoriasis or some other skin condition changed into a reticulosis. Is this just the evolution of the disease or is the reticulosis a new development *caused* by the original dermatosis? If glands from widespread dermatoses are examined they show a reaction to irritation; chronic irritation anywhere may at times produce new growths. May it not be that the prolonged irritation of a chronic skin disease may lead to malignant changes in the skin which show themselves as a reticulosis?

**Dr. Grant Peterkin:** The dramatic response to X-ray therapy of the patient in Sheffield makes it look as if he was in the premycosis group. I would call this case psoriasis and premycotic eruption. Psoriasis is a common disease and we must expect that patients with psoriasis may acquire reticulosis which might not be related.

**The President:** When a case of psoriasis ultimately presents with mycosis fungoides I feel that it is coincidental. This psoriasis started at 10 or 12. The present eruption, like the parapsoriasis lichenoides, is of recent origin. I wondered if treatment had been responsible.

**Reticulohistiocytoma (Type Caro/Senear).**—DENIS SHARVILL, M.R.C.P.

J. N., male, aged 50.

*History.*—Until the onset of the present illness the patient had enjoyed excellent health, suffering no major illness during thirty-five years of military service; on discharge from the Army in June 1957 he was regarded as normal at his medical examination. In April 1957 he had noticed "slight pain and fibrositis" in his right elbow, and during the summer transient severe pain in his instep. During July and August he experienced intense itching of the back for a few weeks. In September there appeared pain and stiffness in the right shoulder. The skin remained normal until November 1957, when symptomless nodules appeared in the skin of his ears and hands, increasing in numbers until early January 1958, since when they seem to be decreasing. In early January 1958 a swelling appeared on the back of each hand causing some interference with finger movements. His general health has remained good throughout, so that he has made light of his symptoms.

*On examination.*—A profuse eruption was present on the fingers, hands and wrists, and on the outer surfaces of the ears, consisting of the following elements: (1) Discrete hemispherical or flatter papules of match-head size or larger. These were of skin colour or bright red and covered by intact, but stretched and shiny, epidermis. Their consistency was firm to very hard. They were attached to the epidermis but not deeply, although the lack of subcutaneous fat on the helices made them seem fixed in those sites. (2) Rather larger streaks, macules, and plaques of larger size—up to 1 cm. or more—of a dusky red or reddish purple hue. (3) Striking lesions of the finger nail-folds just proximal to the nails, 2 to 3 mm. in width and stretching like bands across the digits; these were brownish red in colour and very firm. All the above lesions were painless and non-tender. On the dorsum of each hand was a poorly defined, broad-bean-sized swelling, attached to the extensor tendons; these were slightly tender, and there was limited flexion of the fingers, especially on the left. The right shoulder joint was completely fixed, scapular movement only being present. There was no clinical evidence of involvement of other joints. General examination showed no other clinical abnormalities; there was no evidence of thyroid disorder.

*Investigations.*—The following investigations and tests gave normal or negative results: X-rays of right shoulder region and chest. Hæmoglobin, E.S.R., total and differential white cell count. Serum cholesterol and calcium. Serum proteins, by chemical and electrophoretic investigation. Liver function tests. Rose-Waaler test.

Serum uric acid: 8·6 mg./100 ml. Serum anti-streptolysin "O" titre: 180 units/100 ml.

*Histology* (Dr. V. H. Bowers).—Reticulohistiocytoma. In the centre of the lesion the dermis is packed with multinucleate giant cells, separated from one another by only a few fine collagen fibres, and the overlying epidermis is thinned and has lost its rete ridges. In the dermis at the periphery of the lesion the giant cells are separated by broad strands of collagen, and in a few sections a single small aggregation of lymphocytes is seen in this region also. No other inflammatory cells are present. The giant cells are rounded or oval, but their shapes are modified by the pressure of adjacent cells and fibres. They range in size from 15 microns in diameter to 65 by 40 microns. The smallest cells contain a single nucleus, and the largest about 15 nuclei in each, quite irregularly arranged, and generally the larger the cell the more numerous the nuclei. The cell cytoplasm is mauve in colour in the H. and E. sections, apparently taking both stains; it is almost homogeneous, but with a barely visible fine reticular or vacuolated appearance in a few cells, and a faint basophilic smudging in others. The nuclei are round, oval or slightly indented, and they range in size from 5 microns in diameter to 13 by 10 microns. Many show a well-defined nuclear membrane, with a stippled chromatin pattern. Almost all have a single large, rounded nucleolus about 2 microns in diameter. No Nissl material or nerve axons were demonstrated. The whole of this biopsy was blocked in paraffin, and no tissue was available for frozen sections to stain for sudanophil material.

*Cytodiagnosis.*—Multinucleate giant cells were readily demonstrated in stained smears of scrapings from a nodule. These cells contained no sudanophil material.

*Postscript* (5.3.58).—During the month following presentation the patient received large doses of vitamin A, 480,000 units daily. At the end of this time the nodules had disappeared completely from the hands and fingers and largely from the ears. The tendon sheath swellings had also subsided. The condition of the joints, however, had worsened alarmingly, the other shoulder, both elbows, both wrists, most fingers, and both knees being involved. The pain and stiffness were such that the patient was unable to rise from a chair or to walk more than a few steps. Clinical examination of these joints showed a full range of passive movement with slight crepitus and a remarkable lead-pipe rigidity suggesting muscle spasm. X-rays were still normal. After forcible manipulation of the right shoulder under general anæsthesia a full range of painless movement was obtained, and has so far lasted for ten days. An injection of hydrocortisone into a knee-joint also gave full painless movement. Further special investigations and treatment are at present being carried out in hospital.

ADDENDUM (20.5.58).—The skin is now normal except for three nodules near the right elbow. The joints are painless, movement only slightly limited, and function generally good.

In view of persistent mild dysphagia the patient was referred to Mr. J. B. Blacklay for laryngoscopic examination. He found circumscribed nodules under the mucous membrane of the epiglottis; the appearance of these was unfamiliar to him, but he considered that they might well have been of the same nature as the skin lesions.

Synovial membrane from a knee-joint was heavily infiltrated with multinucleate giant cells similar to those in the skin; no sudanophil material was seen in frozen sections.

**Dr. Robert Warin:** Dr. C. D. Evans, Dr. M. Hewitt and I have recently recorded 4 cases of this condition (*Brit. med. J.*, 1957, i, 1387), making a total of 16 recorded in the literature. Two of these cases were under the care of Dr. J. T. Ingram; one in association with Dr. E. Ritter. The eruption and histology in Dr. Sharvill's case is typical of this condition. In only one of the reported cases did the rash antedate the joint disability but after a period of two years widespread arthritis developed with areas of apparent bone destruction. It seems likely that the patient seen to-day will develop the same state. We felt the condition was related to lipoid disorders in view of the presence of striking multiple xanthelasma palpebrarum in 2 cases and that histochemical investigations indicated that the material in the large giant cells was a lipoid, probably in combination with a polypeptide. We consider the condition to be an abnormality in connective tissue cell metabolism, and not a true reticulosis.

**Dr. Sharvill:** Of the cases reported in the literature, a curiously large number have died from malignant neoplasms.

**Cutaneous Hæmangiomata and Bony Deformities (Klippel-Trenaunay and Parkes Weber Syndrome).**—J. EVERALL, M.R.C.P., and M. FEIWEL, M.R.C.P. (for G. B. MITCHELL-HEGGS, O.B.E., F.R.C.P.).

Mrs. M. P., aged 32.

*History.*—Hæmangiomata of the umbilicus first noticed at the age of 6, followed by similar lesions on the right leg from the age of 11 and later about the face and mucous membranes of the mouth. Hæmangiomata of the legs treated with radiotherapy at Sheffield in 1942 and

similar lesions about the mouth and nose removed surgically at Sheffield in 1949. Severe epistaxis during childhood. No history of epilepsy. Menses regular. Married nine years, no children. General health satisfactory.

*Family history.*—Parents not related. One half-sister had epistaxis in childhood.

*Previous illness.*—Pneumonia, varicella, pleurisy.

*On examination.*—Discrete, bluish, small cavernous hæmangiomata about the muzzle area of the face, tongue and mucous membrane of the mouth. Similar lesions about the umbilicus and on the tips of the first and fifth right toes. Some superficial varicosities about the back of right calf. Multiple radiotherapeutic scars on right thigh and leg. Right leg longer and warmer than left. Right leg showed bony enlargement of the tissues along the right anterior tibial surface, associated with some enlargement of the tissues of the right ankle and right lower leg compared with the left. Multiple superficial venules about the right ankle and across the shoulders. Loud systolic murmur in the precordial region, loudest at apex. No cranial bruits heard. Blood pressure 170/75. Urine normal.

*Investigations.*—E.S.R. 6 mm. in the first hour (Westergren). Blood count normal. X-ray of right lower leg shows small phlebolith-like opacities in the subdermal tissues of the limb at several sites. Right tibia substantially longer than the left and shows periosteal new bone formation of long standing at two distinct sites.

X-*rays.*—Chest: There are irregularities in the right fourth, fifth and eighth ribs anteriorly. These changes are a mixture of expansion, very localized rarefactive foci and marginal sclerotic changes with new bone formation.

Lateral film of right tibia: Shows considerable anteromedial periosteal new bone formation and in the immediately adjacent soft tissues groups of phlebolith-like structures are seen.

Skull shows peculiar appearances of the dorsum sellæ and the posterior clinoids. Hands normal.

ECG and EEG normal.

**Dr. Feiwel:** When this patient was shown at St. John's Hospital I asked how the angioma at the corner of the mouth should be treated, whether by X-rays or by surgery? Those on the legs have responded to X-ray therapy but have left demarcated areas of atrophy. Professor C. G. Rob, who has seen her, suggested surgery but I felt there might be difficulties.

**Dr. R. T. Brain:** I suggest that about 3 minims of tincture of iodine should be injected into the middle of the lesion. I have treated similar lesions very satisfactorily.

The following cases were also shown:

**Metastasizing Sweat-gland Sarcoma.**—Dr. G. Allen, Mr. Norman Tanner, and Dr. M. Feiwel.

**Scirrhous Sweat-gland Adenocarcinoma of Lip.**—Dr. M. Feiwel and Dr. H. Haber.

**Jessner's Lymphocytic Infiltration of the Skin, associated with Chronic Urticaria.**—Dr. Robert Warin.

**Purpura Associated with Hyperglobulinæmia and Systemic Lupus Erythematosus.**—Dr. S. Reiss and Dr. M. Feiwel.

**Sarcoidosis.**—Dr. R. H. Marten (for Dr. D. I. Williams).

**Tuberculosis Cutis Colliquativa Ulcerosa.**—Dr. R. S. Francis and Dr. M. Feiwel.

**(1) Onchocerciasis. (2) Subcorneal Pustular Dermatosis.**—Dr. I. Sarkany.

**Parapsoriasis Lichenoides.**—Dr. P. J. Hare.

**Porokeratosis (Mibelli).**—Dr. R. H. Marten (for Dr. Sydney Thomson).

**Angiomatous Nævus of the Gums.**—Dr. D. I. Williams.

**Erythema Annulare Figuratum.**—Dr. J. Everall (for Dr. G. B. Mitchell-Heggs).

# Section of Proctology

President—HENRY R. THOMPSON, M.A., M.B., F.R.C.S.

[*February* 12, 1958]

## Ano-rectal Anatomy

By Professor E. W. WALLS, M.D.

*London*

BEFORE proceeding to report briefly on certain observations made on the pelvic splanchnic nerves and on the epithelial lining of the anal canal, I will indicate, in response to a request, what anatomists understand these days by the rectum. Anyone conversant with the vagaries of anatomical terminology will appreciate the feeling which prompted the plea; nor is it so simple as it might seem, for apart from changes in the names themselves there has been considerable inconsistency in their use.

According to current terminology the descending colon extends from the spleen to the left side of the brim of the true pelvis, and from there the pelvic colon continues as a somewhat variable loop suspended by the pelvic mesocolon to the middle of the third piece of the sacrum—the point at which the rectum is now considered to begin. In former days, however, the rectum was regarded as commencing at the left sacro-iliac joint, and the peritoneal fold which attached it between this level and the middle of the sacrum was called the meso-rectum; the name sigmoid colon was given to that part of the gut between the left iliac crest and the true pelvic brim. Thus defined, the sigmoid consisted of a proximal part lying in the left iliac fossa covered by peritoneum on its front and sides, and a distal portion of greatly variable length forming a loop, the sigmoid loop or flexure, provided with a mesocolon. This mesocolon together with the meso-rectum are now referred to as one unit, the pelvic mesocolon.

In justification of the present view it may be instanced that the pelvic mesocolon ceases at the third piece of the sacrum, that the appendices epiploicæ and the sacculations characteristic of the colon disappear at this level, and finally that the superior rectal (hæmorrhoidal) artery divides into two branches at the same point.

It is of interest and importance to recall that in 1830, when Houston first gave an account of the valves which bear his name, he described one of the valves as lying on the right "at the upper end of the rectum"; to-day, of course, it would be described as lying within the pelvic colon. This in itself would not matter greatly except that, as Silver (1955) has pointed out, when Houston's words are reproduced in modern accounts of the region "the reader cannot be sure whether they should be interpreted in the sense in which Houston used them, or in the light of the revised terminology".

### THE PELVIC SPLANCHNIC NERVES

These nerves, also called the nervi erigentes, spring from the anterior primary rami of the sacral nerves, their origin usually being given as the II and III, or III and IV. Although their course is well known, Dr. J. Caria Mendes, at present in this country on study leave from Portugal, has carried out a number of dissections in my Department with the special object of investigating how practicable it would be to remove the rectum without damaging the parasympathetic innervation to the urogenital system. In the formalized cadavers on which he worked it was a matter of no great difficulty to trace the nerves from their origin to where they join the corresponding pelvic (sympathetic) plexus on the side of the rectum. In fourteen specimens he found the nerves arose from the III and IV sacral nerves, in no case from the II, and he also noted that running with them in a number of specimens there were considerable contributions from the sacral portion of the ganglionated sympathetic trunk. So closely did the plexus hug the rectum that he was forced to the conclusion, with which I concur, that removal of a rectum affected by carcinoma without serious damage to the parasympathetic pelvic innervation would be a matter of immense difficulty if not impossibility.

### THE EPITHELIAL LINING OF THE ANAL CANAL

The zone to which I wish to direct attention is that above the level of the anal valves, for it was here that I found the greatest variability in epithelial type to occur. On average

the zone in the adult measures 17 mm., and in all of 20 specimens examined the upper part was lined for a variable extent (4–16 mm.) by rectal-type mucosa. The epithelium between the level at which intestinal mucosa ended and the line of the valves, a region which varied from 1–9 mm. in extent, was, however, not of constant type. In some cases stratified columnar epithelium was met with, while in others the epithelium was stratified squamous. This is not the whole story, for in some specimens several different types of epithelium succeeded one another. Thus, stratified squamous of 12 layers or more might be seen to merge into stratified columnar, or into a low stratified polygonal of only 3 or 4 layers. On occasion patches of simple columnar were also encountered in this zone, while in places the appearance of transitional epithelium was suggested.

The wide range of epithelial types which may be found in this zone of the anal canal must be a matter of some importance to pathologists called upon to report on sections from this region, and it is hoped that the findings stated briefly here may prove of service in this connexion.

## The Peutz-Jeghers Syndrome

By THOMAS L. DORMANDY, M.B., B.Sc., F.R.C.S.Ed.
*Captain, Royal Army Medical Corps*

DR. JOHANNES PEUTZ was 71 when he died a few days before Christmas, 1957. He was born in Gröningen and studied medicine at Utrecht. After postgraduate work at a number of Continental universities he settled in practice in The Hague where he became a founder of St. John's Hospital. For many years he was Chief Physician to that hospital. Many honours, including the Fellowship of the Dutch Royal Society, bear witness to the high regard and affection in which he was held in his own country. Internationally his name is now linked with the syndrome of gastro-intestinal polyposis and muco-cutaneous pigmentation which he was the first to describe (Peutz, 1921). The genealogical table of his patient covers three generations with 7 proven and 3 probable cases of the syndrome. 3 members of the family also had nasal or bladder polyps—hence Peutz's original title of "visceral" polyposis.

Like many rare diseases, Peutz's syndrome needed several rediscoveries before it became widely recognized. Greatest credit for this, as well as for establishing the syndrome as a definite clinical entity, must go to Jeghers, McKusick and Katz (1949). They not only gave a masterly account of 10 personal cases; but they also uncovered from the medical, surgical and dermatological literature of the past, several other "probables" and "possibles", including 2 cases reported by Sir Jonathan Hutchinson in 1896. The first patient to be diagnosed in this country—though not the first to be described—was presented to the Clinical Section of this Society by Mr. Norman Tanner in 1951. It is now clear that the abnormal gene responsible for the syndrome is of world-wide distribution: some of the earliest case-reports came from India, South Africa, and the Middle East.

The Peutz-Jeghers syndrome has three cardinal features—gastro-intestinal polyposis, a characteristic pattern of melanin pigmentation of the skin and mucous membranes, and familial transmission by a Mendelian dominant gene (or genes). Gastro-intestinal polyposis does not invariably involve all parts of the gastro-intestinal tract: but it *may* affect any part and sooner or later it always affects the small intestine. According to the segments involved various regional classifications have been suggested; but they may lead to errors in diagnosis and in management. There is a silent time-interval of many years between the peak incidence of symptoms from polyps in the rectum, the small intestine, the colon, and the stomach. The polyps in these various parts seem to erupt at different ages; and some—especially the rectal polyps of childhood—may regress and disappear spontaneously after a few years (Andrén and Frieberg, 1956). In the jejunum and ileum alone the naked-eye growths do not appear synchronously: after the first crop has appeared many months or years may elapse before the next sprouts out; and at operation two polyp-bearing segments are usually separated by still normal-looking gut. This mode of spread is a strong argument against prophylactic "clearing" operations on symptomless patients.

A woman patient, who is now 57, started to have attacks of abdominal colic at the age of 20. For ten years she had numerous negative investigations; and in 1930 she entered a mental home as a voluntary "neurotic" patient. There she was struck down by a particularly violent attack, which led to her first laparotomy. Two small-intestinal intussusceptions were found and resected; and more polyps were identified by palpation in her small intestine and colon. Six months later she was free from symptoms; but, anxious to forestall future episodes before resuming her career as a school-

teacher, she was easily persuaded to "get rid of all her polyps." Accordingly, two elective operations were performed: her small intestine was "cleared" through a number of enterotomies at the first; and her right hemi-colon was removed at the second. After three years of good health she was seized by another attack; and the same surgeon who had operated on her before found at laparotomy another ileal intussusception studded with polyps. This was resected. During the past twenty-two years she has been symptom-free; and, until fourteen months ago, yearly barium investigations have shown no abnormality. Her two most recent double-contrast barium enema pictures, however, again show several moderate-sized polyps in what is now her terminal ileum.

Fortunately, "clearing" operations are not only unlikely to be successful in preventing future obstructive episodes; they are also unnecessary from the point of view of malignant change. In sharp contrast to polyps of the colon and, perhaps, the stomach, small-intestinal polyps do not become cancers—not, at least, in the clinically accepted sense. Histologically many show the classical features of an early, well-differentiated adenocarcinoma, especially apparent invasion of the submucosa and muscularis; but the clinical follow-up always casts doubt on the pathological diagnosis (Dormandy, 1958). One can only guess at possible explanations for this striking dissimilarity between the natural history of polyps in the small and large gut (even in the same patient): here I would merely like to dismiss two obvious ones. First, patients with small-intestinal polyps do, as a rule, live into the cancer age: indeed, many die from cancer arising from one of their rectal or colonic polyps. Second, I do not think that they are saved from developing small-intestinal carcinomas by intussusceptions which precipitate, as it were, timely operations. It is true that the rare and rapidly fatal primary small-bowel carcinoma rarely causes intussusception; but most patients with adenomatous polyps—whether these are frankly innocent or apparently malignant—suffer from self-reducing intussusceptions for many years before they are diagnosed. "There is", as the *Lancet* commented, "something very curious about the resistance of the human small bowel to malignancy. Its mucosa is extensive and it has a high mitotic rate. It lies in direct continuity with the mucosæ of the pylorus, bile-ducts, pancreatic ducts, and colon—areas of high cancer-incidence. If carcinogenic hydrocarbons are fed to rats, those few alimentary adenocarcinomas which do arise are largely confined to the small intestine. [Yet] . . . there is no more remarkable example of this apparent cancer resistance than the uniformly good prognosis of these polypoid lesions, which at any other site of the body could be so confidently labelled pre-malignant [and which are, in fact, often labelled malignant by the pathologist]" (*Lancet*, 1957).

I think that the origin of many small-intestinal polyps from the deeper layers of the bowel-wall accounts for most histological diagnoses of malignancy. Examining serial sections of two operation and post-mortem specimens of small bowel, I found a number of areas of microscopic intramural adenomatosis in parts of the gut which looked normal or almost normal to the naked eye. These microscopic adenomas vary in complexity from simple "vesicles" to more substantial nodules: they tend to be grouped together (often around one or two naked-eye polyps): they interrupt the continuity of the muscle coat: and many show some degree of cellular irregularity (or immaturity) and great mitotic activity. The apparent "invasion" of the deeper layers of the bowel-wall by large naked-eye polyps would seem to reflect their origin rather than an ominous late development in their natural history.

Intussusceptions, often compound, sometimes multiple, occasionally retrograde, almost invariably transient, are the characteristic complication of small-intestinal polyposis: indeed, life with small-intestinal polyps, or even a solitary polyp, could be described as a succession of acute, subacute and chronic intussusceptions. They are the pathological basis of a highly characteristic clinical picture. The patients frequently give a history, going back with intermissions over many years, of brief but sometimes extremely severe attacks of green-apple type of colic. These attacks can strike at any time; but often they come on with great regularity a few minutes after meals, or, even more commonly, shortly after getting out of bed in the morning. Many patients say that during the attacks they have a sensation of a lump or lumps rolling about in their abdomen: and some maintain (probably rightly) that they can even palpate a mass moving about. As a rule the attacks subside spontaneously; or they can be cut short by the patient performing some physical contortion, such as doubling over a chair, or even by pressing on various parts of the abdomen. It can be quite frightening to see a mother vigorously massaging the abdomen of her ill child: but there is no doubt that this can be effective. (In 1925 Barrington-Ward concluded a case report of multiple small-intestinal tumours with the remark, "I have not seen a case before in which it was possible to reduce intussusceptions by simple manipulation through the abdominal wall: [yet] this was done on at least three occasions by two different observers".) The attacks of pain are often heralded by flourishes of loud borborygmi: and during periods of intermission explosive rumblings can be not only a source of social embarrassment but also a warning of more attacks to come.

The transience of the intussusceptions accounts for the disconcertingly rapid changes

in the physical findings. A lump felt with the utmost certainty may not be demonstrable an hour later: an easily palpable or even visible mass, described by the family doctor or the casualty officer as "fixed" in the right iliac fossa, may have moved to the left hypochondrium by the time the patient is examined in the ward. Aspersions may be cast on the clinical acumen of earlier observers, when, in fact, the very impermanence of the physical signs should provide a clue to the diagnosis.

A curious feature of these small-intestinal intussusceptions, which cannot be explained by the mechanisms postulated by Wardill (1925) or Raiford (1932), is that some contain no polyps, even though many polyps may be present in other segments of the bowel (Dubourg *et al.*, 1952). The explanation, I think, lies in the microscopic derangement of the gut-wall, which is far more extensive than the naked-eye picture would suggest: areas of micro-adenomatosis could certainly interfere with normal peristalsis and initiate abnormal waves of contraction.

Melanin pigmentation is the second cardinal feature of the Peutz-Jeghers syndrome. Its cutaneous component is the more striking but the less constant: it consists of light-brown to black macules, varying in number from one or two to many hundred, and in size from those just visible to others three or four millimetres in diameter. Their margins are clearly outlined: and they are characteristically grouped around the mouth, the nostrils and the eyes. The fingers, the palms, the toes and the soles of the feet occasionally carry a few. The mucosal pigmentation is often less conspicuous and lighter in shade; but, as Jeghers insisted (Jeghers *et al.*, 1949), it is the *sine qua non* of the syndrome. The lips and cheeks are always involved; and dark patches can sometimes be found on the palate, the fauces and the conjunctivæ. The polyps and the intestinal mucosa are not pigmented. Wherever they are, the macules are level with the skin or mucous membrane, they are non-hairy, non-vascular and non-irritating: and their number and distribution bear no relationship to the number of polyps or to the severity of the gastro-intestinal symptoms. It is surprising how often extensive facial and especially buccal pigmentation passes unnoticed by doctor, dentist and even close relatives: and what should be a spot diagnosis in more senses than one is not usually made until after laparotomy. On the other hand, the cutaneous spots can be a real nuisance: one child's life was made a misery at school because of his continuously "dirty" lips; and at least one patient has undergone a plastic operation on her lips to improve appearances (Edwards, 1958).

The cutaneous pigmentation is usually present at birth and begins to fade around puberty: but cases where both the macules and the digestive symptoms did not appear until old age are on record (Troxell, 1954). Contrary to what has been suggested by earlier observers, the pigmentation and the syndrome are not confined to dark-complexioned people: amongst 21 cases investigated by myself 4 were fair-haired (Dormandy, 1957).

Like polyposis coli, the Peutz-Jeghers syndrome is occasionally associated with other congenital and sometimes hereditary abnormalities. Apart from bladder and nasal polyps mentioned by Peutz and more recently by Hafter (1954), I have encountered examples (amongst my own patients or in the literature) of associated bronchial adenomatosis, a variety of skeletal and cutaneous defects (especially mild finger clubbing), congenital heart disease, extensive small-intestinal diverticulosis, retarded development, and ovarian disease (Dormandy, 1958; Staley and Schwarz, 1957). Also, like polyposis coli, many cases appear sporadically: and in some members of affected families the pigmentation or the polyposis alone may manifest itself. The exact pattern of the genetic transmission remains to be elucidated.

# Treatment of Ulcerative Colitis with Local Hydrocortisone

By S. C. TRUELOVE, M.D., M.R.C.P.
*Oxford*

A CONTROLLED therapeutic trial of patients with ulcerative colitis carried out by the co-operation of a number of physicians showed that cortisone *by mouth* increased the chances of a patient going into clinical remission within six weeks of starting medical treatment. (Truelove and Witts, 1954, 1955).

The finding that cortisone by mouth is beneficial in cutting short an attack of ulcerative colitis immediately suggested the possibility of using hydrocortisone locally in the colon. It was first necessary to find the best way to introduce hydrocortisone into the colon without it immediately being thrown out by the inflamed organ. I decided to use a drip into the rectum, making use of a blood transfusion giving-set slightly modified to carry a rubber catheter at the end for actual insertion into the rectum. Subsequent experience has shown that this is effective in all but a very few patients. Patients who are not severely ill can carry out this treatment at home without difficulty.

Since 1955 I have given 107 courses of treatment with local hydrocortisone to 80 separate patients, a number of the patients having been treated more than once. These treatments can be divided into four main groups (Table I). The first three groups represent formal

TABLE I.—TREATMENT OF U.C. WITH LOCAL HYDROCORTISONE UP TO JANUARY, 1958

| | Treatment | No. of courses of treatment | Rapid remissions | |
|---|---|---|---|---|
| I | Hydrocortisone (free alcohol) in dilute alcoholic solution. 60–120 mg. HC nightly | 21 | 14 | Truelove (1956) |
| II | Hydrocortisone hemisuccinate sodium in saline. 100 mg. HC nightly | 18 | 11 | Truelove (1957) |
| III | Controlled trial of HC-HSS for 1 week followed by known HC-HSS + antibiotics for 2 weeks | 40 | 29 | To be published |
| IV | Miscellaneous treatments not included in I–III | 28 | | Severe cases<br>U.C. in pregnancy<br>Juvenile cases<br>Long-continued treatment |

studies, the first two of which have been reported (Truelove, 1956, 1957) while the third will be reported in detail shortly (Truelove, 1958). The fourth group consists of a miscellaneous collection of patients.

The first study (Row I in Table I) involved 21 courses of treatment using hydrocortisone itself. Because hydrocortisone has a low solubility in water (though much greater than that of cortisone) the manufacturers supplied it dissolved in 50% ethyl alcohol, in which it is quite soluble. This was diluted with ten times its volume of saline for actual use in the colon and was dripped into the rectum from the modified blood transfusion set (Fig. 1). The result of

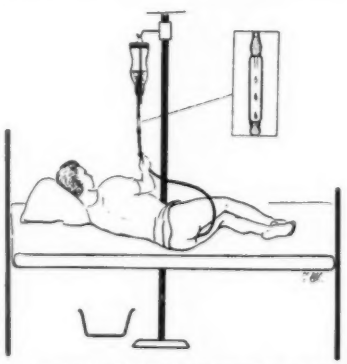

FIG. 1.—Method of self-administration of rectal drip.

this form of treatment was apparently good, because in 14 instances there was rapid clinica remission, i.e. within a few days.

The number of patients who responded to the treatment in this first study seemed to me quite encouraging. The sigmoidoscopic appearances also improved in parallel with the clinical responses. However, there was an odd discrepancy in that the histological responses, as judged by small biopsy specimens taken from the lower colon by means of an instrument devised for this purpose, did not show a corresponding improvement. This raised the possibility that the alcohol which formed part of the diluent for the hydrocortisone might itself be having a bad effect upon the inflamed colonic mucosa and preventing it from healing.

Fortunately, at about this time, Glaxo Laboratories were able to give me hydrocortisone hemisuccinate sodium, which is highly soluble in water. From Row II of Table I, it will be seen that the second study involved 18 courses of treatment given with this agent. The clinical response to hemisuccinate was closely similar to that obtained with hydrocortisone itself for there were 11 rapid remissions. The sigmoidoscopic appearances improved in parallel with the clinical response. Moreover, a favourable clinical response was accompanied by a definite improvement in the colonic mucosa, as judged from biopsy specimens. It therefore appears that a water-soluble compound such as the hemisuccinate is better than hydrocortisone itself, because, on first principles, it seems wise to choose an agent with which the actual diseased tissue shows evidence of reverting toward normality.

At this stage it seemed imperative to put this form of treatment to a formal test to make quite sure that the favourable judgment which I had formed on clinical impressions alone was indeed true. I therefore carried out last year a planned therapeutic trial involving 40 courses of treatment. The first part of the trial involved the use of either real hydrocortisone hemisuccinate or a similar-looking inert preparation. These were prepared by the manufacturers and nobody at Oxford knew which was which until the study was finished. The patients were allotted at random to one or other and this "blind" part of the trial lasted for one week. In every case, this was followed by two weeks of treatment with known hydrocortisone hemisuccinate sodium, together with penicillin and streptomycin added to the rectal drip, because I also wished to find out whether the addition of antibiotics would improve the action of the hydrocortisone and bring into remission cases that did not respond to hydrocortisone alone. At the end of the first week, out of 20 courses of treatment given with the inert preparation, only one resulted in clinical remission; whereas out of 20 courses of treatment with real hydrocortisone hemisuccinate, 11 patients were in remission. The difference is considerable and is statistically highly significant ($P < \cdot 01$). A fortnight later, after known treatment with hydrocortisone and antibiotics, the two groups were closely similar. We may therefore take it as reasonably certain that hydrocortisone hemisuccinate dripped into the rectum has a real effect in bringing about clinical remission in quite a large proportion of the patients. In other words, its action is pharmacological and not due to any placebo or psychological effect.

Antibiotics do not make much overall difference, sometimes being helpful and sometimes being deleterious, but this point will not be discussed further here except to say that they should not be used routinely.

Group IV of the treatments shown in Table I is a miscellaneous collection of patients who have not been included in any of the previous three studies for a variety of reasons. Only one or two points will be mentioned:

*Severe cases.*—In general, the local treatment has been used for patients suffering only from mild or moderate attacks of ulcerative colitis. This has been done for two reasons:

(1) A severe attack of ulcerative colitis is a dangerous illness and it seems right to gain a good deal of experience with any new form of treatment in the less severe cases before applying it to those patients who are gravely ill.

(2) An additional reason has been that a second large-scale trial is taking place in 12 hospital centres in this country of the systemic use of cortisone and of ACTH and the more severe cases that I have seen have been admitted to this national trial.

However, a few patients with severe attacks have been given the local treatment, particularly when they have failed to respond to the corticoids used systemically. In general the results have been highly favourable. However, various technical problems arise when treating severe cases by this method: these are being studied at present.

### Ulcerative Colitis in Pregnancy

It is known that ulcerative colitis in pregnancy can be severe and is at the least a grea inconvenience and trouble to the patient if the symptoms persist throughout the pregnancy Two patients having symptoms during pregnancy have been treated with a nightly rectal dri of hydrocortisone which has been continued until after the baby has been born. The result have been excellent in both patients.

### Juvenile Cases

I do not see many children with this disease but three that I have seen in the last year and have treated by this method have all done well. These have been treated in the same way as the pregnant patients, in that treatment has been continued for months rather than for two or three weeks. I mention this point because I think it possible that this will be the future method of choice when a favourable response is obtained to local treatment.

### Long-term Results

The use of hydrocortisone locally, even when it brings about remission, does not mean that these patients are going to be free from further attacks of the disease. Indeed, there is no known medical treatment which will guarantee freedom from recurrent attacks once a person has suffered from this illness. However, it should not be thought that rapid relapse is particularly likely to occur when the treatment is stopped. Indeed, immediate relapse is unusual although relapse over the course of the next few months is fairly frequent. Some patients have remained in perfect remission after a single course. For example, the first patient who was treated two and a half years ago has been symptom-free ever since.

Some idea of the early long-term results can be gained from considering what has happened to 15 patients who responded well to treatment in 1955 and 1956. 6 of them have remained in perfect remission; 7 have had one or more recurrences but have responded swiftly to further courses of local treatment; and 2 have had recurrences which did not respond to a further course so that alternative treatment was necessary.

## Observations on the Management of Idiopathic Proctitis [*Abridged*]

By A. C. Newell, M.D., M.R.A.C.P., and F. Avery Jones, M.D., F.R.C.P.
*London*

These observations are part of a larger study of the natural history of idiopathic proctitis, and are based on the study of 150 patients attending the out-patients at St. Mark's Hospital in the six and a half year period from January 1951 to June 1957. They were patients with typical sigmoidoscopic appearance but with minimal X-ray evidence of disease of the colon itself although undoubtedly a proportion of patients had the same inflammatory process extending upwards into the sigmoid. In the series of 150 there were 94 females and 56 males. Of the 150 cases follow-up information had been obtained from all but 6 of them; 50 at the time of last examination had continuing symptoms and of these 12 had had extension of the disease process often involving the entire bowel and necessitating surgical treatment.

The view was firmly established from this survey that idiopathic proctitis was one and the same disease as ulcerative colitis but in a localized and milder form.

Observations were made on the effect of treatment with prednisone and, initially, a comparison was made between three weeks' treatment with calcium lactate and the same period with prednisone taking alternate cases. Of the 13 patients treated with calcium lactate 9 were not improved or worse at the end of three weeks compared with only 1 out of 10 treated with prednisone who had not improved or got worse. Altogether 44 patients were treated with prednisone and at the end of treatment 16 had no symptoms with normal sigmoidoscopic appearance, 12 had no symptoms with low-grade proctitis present, 11 had persistent symptoms and signs but improvement in both, only 5 showed no improvement. Within three months, however, another 11 had relapsed and needed further treatment. The patients were all treated in the out-patients' department starting with 20 mg. three times a day for one week reducing the dose to 15 mg. three times a day for the second week and then 10 mg. three times a day for another two or three weeks subsequently tailing the dose off. There were side-effects in half the patients but these proved temporary only. One patient developed diabetes, 5 had indigestion and 6 a moderate degree of acne. Symptoms all responded to dose reduction and cessation of treatment.

## Recurrent Synovitis of the Knee

By PETER R. FRENCH, F.R.C.S.
*London*

THE purpose of this communication is to trace the progression from trivial injuries to the knee, to recurrent synovitis and the eventual development of osteoarthritis. I believe that if we explored the knee earlier we might delay the development of osteoarthritis. This paper is based on the findings in the last 305 knees operated on in St. George's Hospital, London, and St. Peter's Hospital, Chertsey.

A joint effusion occurs for two main reasons; the first is a micro-organism and the second internal derangement. It is a commonplace that repeated locking of a knee by a bucket-handle tear of a meniscus causes recurrent effusion into the joint. What is not so well realized is that the condition labelled chronic non-specific synovitis is in the majority of cases also due to mechanical upset. Earlier recognition of this fact and operative intervention may postpone the development of osteoarthritis. The two main difficulties in the past have been, (1) the conditions that lead to osteoarthritis are usually present long before there is radiological evidence of them; and, (2) there has been some hesitation about performing an adequate exploration of the knee-joint. It is questionable whether quadriceps insufficiency is ever by itself a cause of swelling of the knee, and, indeed, in poliomyelitis does not produce an effusion. Synovial biopsy in the past has been made through a minute incision, synovial hyperplasia and hyperæmia are noted, and microscopically there is a non-specific inflammatory change. The guinea-pig survives the inoculation.

The clinical picture is one of recurrent swelling of the knee, with aching pain which is aggravated by activity and settles with rest. There is often stiffness after sitting and there may be painful giving way due to a frayed meniscus or non-radiopaque loose bodies. The knee is found to be slightly warm, may have a moderate effusion and the quadriceps is somewhat wasted. There is some limitation of movement and tenderness along the joint line and at the reflection of synovial membrane from articular margins. The localization of tenderness is often misleading, as the causative lesion may be out of reach of the palpating finger. The patient is otherwise well and no other joints are affected. Radiographs are usually normal but may show a loose body or slight irregularity in the contour of the articular surfaces. The majority settle with rest but flare with activity. Physiotherapy often aggravates the condition. The subsequent course is variable; a few are found to be disease of the synovial membrane such as villo-nodular synovitis or synovial chondromatosis. A small proportion several years later will develop polyarthritis. We are discussing the remainder.

As opposed to the old-fashioned form of biopsy, adequate exploration of this type of knee discloses lesions of the meniscus, or chondromalacia of the patella producing wearing of the articular cartilage of the femoral condyle. This is accompanied by redness of the synovial membrane and free fluid containing pieces of articular cartilage or meniscus debris.

The normal wear and tear of articular cartilage with advancing age has been described in detail; increased wear of one section of articular surface may not be discovered unless the whole of the patello-femoral and femoro-tibial articulations is exposed. Radiological evidence of cartilage wear will not be present until the changes are irreparable.

Figs. 1–3 illustrate mechanical lesions with changes in the articular cartilage associated with a non-specific inflammatory reaction in the synovial membrane.

Fig. 1 shows a worn area on the articular surface of the patella with a corresponding area of wear high up on the femoral condyle. The synovial membrane was markedly inflamed and there was free fluid in the joint containing pieces of articular debris. The radiograph was normal.

Fig. 2 shows a frayed and degenerate meniscus which is licking at the femoral condyle low down; the condyle is only worn where the meniscus is in contact with it and the articular cartilage is normal elsewhere.

FIG. 1.

FIG. 2.

FIG. 3.

Fig. 3 depicts the knee of a boy aged 14 who presented with symptoms and signs indistinguishable from a tuberculous synovitis. The history included a kick on the same knee by a cow at the age of 8. The excrescence seen on the articular surface of the patella consisted of fibro-cartilage growing from a small circular defect in the cartilage. The synovial fluid contained pieces of similar fibro-cartilage as did the synovial membrane which was taken for section. Radiographs were normal. After removal of the excrescence the knee settled down completely.

The mechanism of the lesion producing the synovitis may sometimes be in doubt. Patello-femoral wear following a recurrent dislocation of the patella is obvious; but subluxation or incongruity of the patello-femoral joint is probably commoner and less obvious. Trauma to the knee-cap leading to damage of the articular cartilage on the patella or femur must be

very common in childhood and adolescence. Again, a major incident tearing a meniscus in a footballer is easy to understand; what is less commonly appreciated is the damage that may be sustained by a meniscus in everyday use.

Microscopy of the centrifuged deposit of synovial fluid often shows fragments of articular debris. The synovial membrane shows increased vascularity with a non-specific inflammatory reaction; occasionally fragments of debris may be found incorporated in it. These findings are supported by animal experiment.

Lloyd-Roberts (1953) discussed the influences of articular cartilage shed from joint surfaces in severe osteoarthritis of the hip-joint upon the symptoms of the disease and concluded that these were due to the taking up of debris by the synovial membrane. We are concerned with earlier changes occurring in the knee. We believe that the synovial membrane is affected in mechanical upsets by acting as a scavenger and removing the pieces of debris from the joint; the debris in the synovial membrane sets up areas of inflammation not unlike a foreign-body reaction. With activity showers of articular debris are cast off; with rest the synovial membrane has a chance to settle down; hence the temporary benefit of splinting. In time, continued inflammation of synovial membrane and capsule gives rise to fibrosis which produces the clinical symptoms and signs of osteoarthritis; the latter is not commonly diagnosed, however, until there is radiological evidence of it. A frayed or damaged meniscus may destroy the articular cartilage of the femoro-tibial compartment of the knee. The patello-femoral compartment may become worn by the peculiar stresses involved in the patello-femoral joint and the susceptibility of the knee-cap to trauma; particularly is this seen in recurrent dislocation or subluxation of the patella. It is felt that earlier recognition of these conditions by exploration of the knee-joint with removal of a frayed meniscus or a worn knee-cap might do much to ward off the crippling condition of osteoarthritis of the knee.

Synovitis is the warning light. If the synovitis is recurrent or persists for more than three months the knee should be explored. This involves an adequate incision to enable one to examine the patello-femoral and femoro-tibial compartments, as a small opening often fails to disclose the pathology. This has been our practice for the last three years; we have found it rewarding and have not found an increase in the number of complications or the length of stay in hospital.

## Arthrodesis of the Great Toe

By A. C. Bingold, M.B., F.R.C.S.

*London*

Should a patient suffering from hallux valgus or hallux rigidus have an arthrodesis or an arthroplasty? As can be seen from the review of the recent literature presented in Table I there is a division of opinion; some opinions are based on very small series. The purpose of this paper is to present a simple technique of arthrodesing the first metatarsophalangeal joint together with the results of a series of 32 arthrodeses comprising both hallux valgus and hallux rigidus cases and to state the indications for either arthrodesis or arthroplasty.

Table I.—Arthroplasty or Arthrodesis of the Great Toe: Review of Recent Literature

| Authors | Treatment recommended for Hallux valgus | Treatment recommended for Hallux rigidus | No. of toes treated | Type of operation reviewed |
|---|---|---|---|---|
| Thompson and McElvenny (1940) | Arthrodesis | Arthrodesis | 14 | Arthrodesis |
| Glissan (1946) .. .. .. | Arthrodesis | Arthrodesis | No. not given | Arthrodesis |
| Smith (1952) .. .. .. | Arthrodesis | Arthrodesis | 16 | Arthrodesis |
| McKeever (1952) .. .. .. | Arthrodesis | Arthrodesis | 56 | Arthrodesis |
| Bonney and Macnab (1952) .. | Arthroplasty | Arthrodesis | 518 | Arthroplasty |
| Cleveland and Winant (1950) .. | Arthroplasty | Arthroplasty | 193 | Arthroplasty |
| Jordan and Brodsky (1951) .. | Arthroplasty | Arthroplasty | 161 | Arthroplasty |
| Cymble (1956) .. .. .. | Arthroplasty | Arthroplasty | 26 | 10 arthrodeses<br>16 arthroplasties |

*Operative technique.*—Before the operation the height of heel the patient wishes to wear is ascertained. A block of corresponding height is then placed under the unshod heel. The angle formed by the first metatarsal and its phalanx is then measured and a pattern is cut from a piece of sheet rubber. Experience has shown that if the angle exceeds 25 degrees arthrodesis should not be attempted.

Through a medial incision the first metatarsophalangeal joint is opened and the invariabl osteoarthritic medial sesamoid is removed. After resection of the articular cartilage th bone ends are shaped with special convex and concave reamers. Using the pattern it i now easy to adjust the great toe at the predetermined angle. Toe and metatarsal may b held together either with a compression device or more simply and safely with an obliquel placed screw (Fig. 1). It is wise to protect the arthrodesis in all cases with a plaster slippe

FIG. 1.—Method of holding bone ends together with an obliquely placed screw.

FIG. 2.—Footprints. Left after Keller's operation. Right after arthrodesis.

FIG. 3.—Foot of patient suffering from hallux rigidus X-rayed in the pushing off phase.

applied over ample padding. Weight bearing is not permitted until the plaster slipper, stitches and any compression device are removed at the end of four weeks. Radiographs are taken and, if the arthrodesis is solid, walking is allowed, but it may be necessary to protect the arthrodesis for a further two to three weeks with a plaster slipper on which the patient can walk. Two to three months after the operation the patient can wear his shoes again.

*Method of study*.—Each patient was personally followed up by the writer. After clinical examination the patient was shown a questionnaire with 4 subjective functional grades and asked to place himself in one of the grades. Grade I, feet normal; Grade II, much improved; Grade III, little if any improvement; Grade IV, worse.

*Hallux valgus series*.—6 patients, 2 male and 4 female, were operated on, 2 of them bilaterally so that eight great toes were available for study. The average age was 53 years. The average follow-up was 11·8 months.

The anatomical result was satisfactory in all cases although in one patient the toe had been fused at a wrong angle necessitating a second operation. The best angle of fusion was 15–20 degrees of dorsiflexion of the great phalanx. There were no non-unions. Subjectively 3 were in Grade I and 5 in Grade II.

5 patients with seven arthrodesed toes had hard skin under their arthrodesed joints which indicated active use of the first digital ray in walking. But one patient with a reversed metatarsal arch, placed in Grade II, put most of her weight on her third metatarsal head. There was no sepsis and no patient had a painful interphalangeal joint.

*Hallux rigidus series*.—22 patients, 9 male and 13 female were operated on, 2 of them bilaterally, making twenty-four great toes available for study. The average age was 45 years. The average follow-up was 14·1 months.

Subjectively 10 were in Grade I, 11 in Grade II, and 3 in Grade III. 2 patients only were dissatisfied. One of these with two arthrodesed toes was a psychopath who had been offered a leucotomy. The other was bitterly disappointed that her toe should now be fixed, although this had been explained to her before the operation. Clinically both patients had well united non-tender arthrodeses with the toe fixed at a correct angle.

The angle of fusion was satisfactory in all cases. The best angle was found to be 15–2 degrees of dorsiflexion of the first phalanx if the interphalangeal joint was normal or had flexion contracture, but if the interphalangeal joint was hypermobile, the best position o the first phalanx was in line with the first metatarsal.

patients on whom a compression device had been used had painless non-unions, one in Grade I and two in Grade II. Clinically their arthrodeses were solid. Only 7 patients with eight arthrodesed great toes had hard skin under their arthrodesed joints and first phalanges. They were, therefore, making full use of the great toe in the final stages of propulsion.

Only one patient required removal of the screw. Sepsis occurred only once necessitating curettage of a small abscess of the first phalanx. Two years later the architecture of this bone was normal, the arthrodesis was solid and the patient had no pain.

No patient had a painful interphalangeal joint. Patients with contracted interphalangeal joints could only wear a heel of a particular height, but patients with a hypermobile interphalangeal joint were not so restricted, and one patient habitually wore court shoes with 3 in. heels.

## Discussion

To understand how arthroplasty and arthrodesis relieve pain in the great toe it is necessary to examine footprints.

A successful arthroplasty for hallux valgus converts a painful great toe into a functionless but painless appendage and weight is borne on the outer four metatarsal heads (Fig. 2). This result is achieved by either Mayo's or preferably Keller's operation. Arthroplasty is the method of choice for most cases of hallux valgus but it tends to aggravate metatarsalgia by throwing an extra load on already painful metatarsal heads, and is, therefore, contra-indicated in all cases of metatarsalgia.

If the metatarsophalangeal joint of the great toe is not osteoarthritic McBride's operation, which restores the shape of the toe to normal without destroying its function, is obviously preferable.

A successful arthrodesis produces a strong great toe on which weight is borne and which plays its part in the final stages of propulsion (Fig. 2). Any tendency to metatarsalgia is therefore, lessened. Arthrodesis is of special value to patients suffering from hallux rigidus because they have an abnormal gait compressing their first great toe-joint in walking (Fig. 3). After an arthroplasty for hallux rigidus this abnormal gait persists, causing compression of the newly made joint and in active patients recurrence of pain.

The above considerations have produced the following schemes for the operative treatment of hallux valgus and rigidus (Tables II and III).

Table II.—Operative Treatment of Hallux Valgus

| Type of case | Treatment |
|---|---|
| Patients up to 45 years of age without osteoarthritis. | McBride's operation |
| Patients over 45 years of age and younger patients with osteoarthritis | Arthroplasty (preferably Keller's operation) |
| Patients with severe metatarsalgia, e.g. caused by dorsal dislocation of the second toe | Arthrodesis plus excision of painful metatarsal head |

Table III.—Operative Treatment of Hallux Rigidus

| Type of case | Treatment |
|---|---|
| Active patients— including women with hypermobile interphalangeal joints. | Arthrodesis |
| Inactive patients | Arthroplasty |

Osteoarthritis of the interphalangeal joint is an absolute contra-indication to arthrodesis. So far osteoarthritis has not been observed as a complication of arthrodesis, althoughsome of the cases were operated on more than five years ago.

# Abduction Osteotomy as a Salvage Operation in Fracture of the Neck of the Femur

By A. J. HARROLD, F.R.C.S.
*London*

THE factors responsible for failure of union in fractures of the neck of the femur are not yet fully understood. With internal fixation failure results in about one-third of cases. We believe that the trouble often lies in the fact that blood shed into joints does not clot and become organized by granulation tissue as it does elsewhere. This paper relates our experience in trying to salvage these cases by abduction osteotomy of the femur.

Through angulation of the neck, the fracture site may be placed below the head so that the body weight no longer pushes the head downward past the fracture surface but directly against it. The conversion of shearing forces to impacting ones enhances immobilization of the fracture and encourages union. The operation may be contrasted with McMurray's osteotomy, which is a displacement osteotomy not an abduction one; by bringing the femoral shaft under the acetabulum it restores stability to the hip. With the abduction osteotomy, however, the same effect is obtained together with three further advantages—an increased chance of obtaining union of the fracture, a slight gain in leg length due to the vertical disposition of the neck, and thirdly a stretching of the abductors which helps to eliminate a Trendelenburg gait.

The technique is as follows: the anæsthetized patient is placed on the orthopædic table after manipulative reduction of any displacement present. The nail previously inserted is removed. The guide wire is placed more horizontally than usual, starting very close to the base of the great trochanter (Fig. 1). In calculating the length of the nail it is wise to leave at least 3/8 in. clearance between the tip of the nail and the hip-joint. The amount of abduction to be obtained is then assessed. We usually aim at an angle of about 40 degrees. A nail-plate is selected so that the angle between the shaft of the femur and the plate is about this amount. This demands a 150 degree or 160 degree nail-plate. After it has been driven home a wedge of bone with a 40 degree apex is removed. Preliminary drilling of the bone enables a clean osteotomy to be done. The lower margin of the wedge is best placed transverse to the line of the femur. The upper margin comes out just below the base of the nail. After removal of the wedge the plate together with the upper fragment is adducted on to the femoral shaft, the orthopædic table being adjusted to permit this, and a Loman's clamp is applied until the screws have been inserted.

The only special precaution taken afterwards is that we avoid passively adducting the leg. The patient lies free in bed, practising exercises, and is able to resume walking after eight weeks. In fact some of the more elderly patients may be allowed to sit out of bed long before this time.

We have done this operation in 23 patients in whom the fracture has redisplaced following primary nailing (Table I).

TABLE I

| | |
|---|---|
| Number of patients: .. .. .. .. | 21 female, 2 male |
| Age 39–83 .. .. .. .. .. | Average age 69 |
| Interval between fracture and osteotomy | |
| 12 days to 17 months .. .. .. .. | Average 11 weeks |
| RESULTS | |
| Further redisplacement .. .. .. (10 days to 15 months later) | 7 cases |
| Fracture united six months after osteotomy .. | 11 cases |
| Uncertain .. .. .. .. .. | 5 cases |

The assessment of results in fractures of the neck of the femur is notoriously difficult. What is certain in these patients is that in 7 complete redisplacement of the fracture has occurred. In 11, as judged clinically and radiologically at least six months from the operation, the fracture has united; 9 of these patients have been followed for over a year. In 5 the result is uncertain, either because the duration of follow-up is too short, or because although redisplacement has not occurred, radiographic union of the fracture is not present. Thus the fracture has probably united in over half the patients.

FIG. 1.

FIG. 2.

FIG. 3.

Fig. 2 is a reproduction of the radiograph in a successful case. Excellent function is usually associated with such appearances. If union has not been secured a tolerable functional result may still be obtained. A woman of 43 was still able to ski three years after her osteotomy when the radiographic appearances were as shown in Fig. 3. The hip hurts but is stable with no Trendelenburg dip. In the presence of severe pain a Girdlestone pseudarthrosis is probably the best treatment.

A relatively frequent occurrence has been penetration of the nail through the head from impaction and absorption at the fracture line. The tip of the nail may enter the hip-joint. We then prefer to shorten the nail rather than remove it completely. One or other operation has been necessary in 8 of the patients. Even when considerable absorption of the neck has occurred union may still be obtained.

This is a possible treatment for the "failed nail", the fractured neck of femur that has "fallen to bits" after internal fixation. It is technically easy and not a severe ordeal for the patient. The after-care is simple. Union of the fracture may be expected to follow in over half the cases. If union fails a reasonable palliation may be obtained. In the absence of a universally successful treatment for this condition abduction osteotomy deserves to be more widely known and used.

## Arterial Homografts in Injuries of the Extremities

By JÖRG BÖHLER, M.D.
*Linz, Austria*

FRESH traumatic ruptures of an artery endanger the injured limb. Therefore continuity of the vessel should be restored as soon as possible. End-to-end anastomosis is usually possible only after clean-cut trauma. In most cases the artery is torn by a blunt force and the arterial wall is damaged over a considerable length; therefore, after resection, direct suture is not possible because of tension. After traumatic rupture of an artery the results of direct suture are generally not satisfactory and deep-frozen or freeze-dried homografts should be used. We tried direct suture of a torn popliteal artery three times without success. In all 3 cases the site of the anastomosis clotted. Only since we began using arterial grafts have we successfully restored patent vessels and preserved limbs. In cases with extensive damage to the arterial wall, with or without clotting, we feel also that the artery should be resected and a homograft be substituted. We have not tried heteroplastic or alloplastic arterial grafts, because in the extremities the results are not satisfactory.

In addition to shock treatment with sufficient blood transfusions the following points should be observed:

(1) The operation should be performed without delay, if possible within the first eight hours, as after this time the chances for complete recovery diminish rapidly. However, restoration of arterial continuity should still be tried after eight hours because the limb can still be viable due to some collateral circulation.

(2) During the preparation for the operation arteriograms should be made to decide the exact level of the interruption.

(3) Operative exposure must be sufficient to recover both stumps and to provide ample space for the anastomoses. Flexion creases of joints should not be crossed by the incision at right angles.

(4) The artery must be resected until normal arterial walls are present on both stumps.

(5) In order to avoid additional damage to the circulation, the operation should not be performed under a tourniquet.

(6) During the operation heparin should be injected into the arterial stumps. Post-operatively no anticoagulants should be used because a hæmatoma will form with consequent infection. After infection thrombosis of the anastomosis is almost inevitable.

(7) Suture technique should be exact and as atraumatic as possible. Either silk No. 000000 or a 0·1 mm. plastic thread should be used. The type of suture seems not to be of major importance. Usually two everting mattress sutures and a running stitch are used. If possible the graft should be of the same calibre as the torn artery; otherwise the major artery should be narrowed by a wedge resection or the lesser artery cut obliquely.

(8) Around the anastomoses there should be no dead spaces in order to avoid hæmatoma formation.

(9) Strict asepsis and the use of post-operative antibiotics are important.

(10) If there is already ischæmia of the limb with swelling of the muscles, extensive fasciotomy should be performed.

(11) Concomitant fractures should be stabilized by osteosynthesis. In the shafts we use intramedullary nails and at the condyles either crossed wires or bolts and screws.

(This presentation was illustrated with an excellent film of arterial grafting in a case with rupture of the popliteal artery after a hyperextension fracture of the tibial plateau.)

# Section of General Practice

President—G. M. KERR, M.B., L.R.C.P., F.F.A.R.C.S.

## DISCUSSION ON EMERGENCIES IN GENERAL PRACTICE

**Dr. R. M. McGregor** (Hawick):

*Surgical Emergencies*

The family doctor is rarely called upon to undertake surgical procedures which are immediately life-saving in character; he is, however, called upon to make decisions and those practitioners associated with hospital beds are, in addition, expected to undertake a certain amount of useful surgery. I propose, therefore, to show the surgical cases I have encountered in the Cottage Hospital with which I am associated.

### OUT-PATIENTS

During the five years, 1952–1957, 477 patients were treated for conditions of a surgical nature. Table I shows them in their order of frequency. 10 of these cases were transferred to a larger hospital. The remainder were a personal responsibility.

TABLE I.—OUT-PATIENTS COTTAGE HOSPITAL 1952–1957

| Surgical (477) | | Transferred |
|---|---|---|
| Wounds | 90 | 3 |
| Fractures and dislocations | 77 | 5 |
| Sprains and strains | 75 | — |
| Septic conditions | 65 | — |
| Cysts and warts | 43 | — |
| Varicose conditions | 43 | — |
| Nasal conditions | 21 | — |
| Removal of foreign bodies | 15 | 1 |
| Joint conditions | 12 | — |
| Dental extractions | 12 | — |
| Burns and scalds | 10 | — |
| Gynæcological conditions | 7 | — |
| Urinary conditions | 6 | — |
| Appendicitis | 1 | 1 |
| | 477 | 10 |

Wounds of varying severity were the most common condition, and the hands and wrists (43 cases) were the regions most frequently involved. Wounds of the face were probably the most troublesome, since there was the need for a good æsthetic result. Sprains and strains (75 cases) can be the cause of prolonged invalidism. This is particularly evident when ligamentous structures of the shoulder-joint are severely damaged. The knee and ankle joints in the adipose and athletic individuals are also tardy of repair. The assurance given by a negative X-ray has frequently accelerated recovery. The outlook in septic conditions (65 cases) has been completely altered by the introduction of the sulphonamides and antibiotics. Strains resistant to penicillin have not been frequently encountered in this neighbourhood. This may be influenced by always using large doses when it is decided to administer penicillin. The early use of large doses immediately a finger becomes painful following the prick of a pin or needle, or when the breast of a nursing mother shows an area of localized tenderness, probably prevents more serious infection. The remainder of the conditions treated reflect a pleasure in doing odd jobs: the shelling out of sebaceous

cysts, the catching of a good crop of nasal polypi, and the removal of a variety of foreign bodies from every conceivable orifice give variety to a day's work.

A renewed interest in the injection treatment of varicose veins is shown by treating 63 cases. In these cases when a satisfactory clot is obtained the vein is opened and the clot expressed. This is followed by tight bandaging, and the hope is that recanalization will be prevented.

Table II shows the fractures and dislocations treated as out-patients. 5 of these cases were transferred to a larger hospital. It is understandable that upper limbs were in the majority when treatment was being given as out-patients.

TABLE II.—OUT-PATIENTS COTTAGE HOSPITAL 1952–1957

Fractures and Dislocations (77)

| Upper limbs | | Lower limbs | |
|---|---|---|---|
| Colles fracture | 28 | Potts fracture | 8 |
| Carpus and metacarpus | 16 | Tarsus and metatarsus | 3 |
| Humerus | 4 | Tibial shaft | 1 |
| Radius and ulna | 4 | Femur | 1 |
| Clavicle | 2 | Patella | 1 |
| Phalanges | 1 | | |
| Olecranon | 1 | | |
| | 56 | | 14 |
| Ribs | 3 | Dislocations | 4 |

IN-PATIENTS

Patients were admitted for observation and diagnosis as well as for treatment. The diagnosis was a personal responsibility but the treatment was often carried out by the visiting specialists. During the nine years, 1948–1957, 546 patients whose condition was of a surgical nature were admitted under my care. Table III shows these conditions in

TABLE III.—IN-PATIENTS COTTAGE HOSPITAL 1948–1947

| Surgical (546) | | Transferred |
|---|---|---|
| Orthopædic conditions | 117 | 13 |
| Gynæcological conditions | 114 | 0 |
| Ear, nose and throat conditions | 63 | 1 |
| Hernia and hydrocele | 42 | 0 |
| Septic conditions | 38 | 1 |
| Cancers | 33 | 12 |
| Varicose veins, ulcers and hæmorrhoids | 30 | 0 |
| Peptic ulcers | 28 | 3 |
| Genito-urinary diseases | 26 | 3 |
| Diseases of appendix, gall-bladder and pylorus | 23 | 3 |
| Cuts and bruises | 17 | 0 |
| Cysts, lipoma, bursæ, &c. | 8 | 0 |
| Dental extractions | 4 | 0 |
| Burns and scalds | 3 | 1 |
| | 546 | 37 |

order of frequency. Since orthopædic and gynæcological conditions top the list and contain most of the emergencies they are given in greater detail in Tables IV and V.

TABLE IV.—IN-PATIENTS (SURGICAL) COTTAGE HOSPITAL 1948–1957

Orthopædic conditions (117)

| Fractures: | | | | | |
|---|---|---|---|---|---|
| Upper limbs | | Head, neck and body | | Lower limbs | |
| Colles fracture | 18 | Skull | 8 | Potts fracture | 19 |
| Radius and ulna | 8 | Ribs | 4 | Femur | 13 |
| Humerus | 3 | Pelvis | 1 | Tarsal and metatarsal | 4 |
| Condyle avulsion | 1 | | | Tibia and fibula | 4 |
| | 30 | | 13 | | 40 |

| Dislocations: | | | |
|---|---|---|---|
| Elbow | 1 | Sprains and strains | 10 |
| Shoulder | 2 | Other orthopædic conditions | 21 |
| | 3 | | 31 |

TABLE V.—IN-PATIENTS COTTAGE HOSPITAL 1948–1957

Gynæcological Cases (114)

| Gynæcologist | | Own cases | |
|---|---|---|---|
| Uterine prolapse .. | 18 | Dilatation and curettage | 47 |
| Hysterectomy .. .. | 5 | Abortions .. .. | 24 |
| Ovarian cyst .. .. | 3 | Salpingography .. .. | 9 |
| Sterilization .. .. | 1 | Salpingitis .. .. | 1 |
| Gilliam operation .. | 1 | Removal of pessary .. | 1 |
| Perforated uterus .. | 1 | Antepartum hæmorrhage | 1 |
| Uterine polypi .. .. | 1 | | |
| Rectovaginal fistula .. | 1 | | |
| | 31 | | 83 |

The ear, nose and throat conditions are no longer the cause of urgent emergencies. There were 51 tonsillectomies performed by the visiting consultant. The septic conditions varied from infections of the hand to ischio-rectal abscesses. 3 cases were real emergencies since they were suffering from acute osteomyelitis. A high fever in a young person complaining of pain in a limb requires a blood culture. Pencillin should then be administered in large doses at frequent intervals without waiting for the result of the culture. The continuing of penicillin injections for some twenty-one days can be very trying for a young person. The cases of cancer were an exercise in diagnosis; some had already had treatment and were admitted because of the development of secondaries. Others received their operative treatment from the visiting surgeon. 12 were sent to a larger hospital because of the need of extensive surgery. The varicose conditions included 13 cases of hæmorrhoidectomy performed by the visiting surgeon.

The peptic ulcers included four patients with a localized perforation treated by conservative means. The 3 patients transferred were thought to need gastrectomy. 2 of the patients had severe hæmatemesis and were given blood transfusions. Among the genito-urinary conditions there were 10 cases of urethral caruncle in the female. This is a condition which is often overlooked as a cause of much discomfort in the female. They were all treated by the electrocautery. Diseases of the appendix were in the province of the visiting surgeon; 15 were interval appendicectomies. One case of pyloric stenosis required operative treatment. The cuts and bruises were conditions of some severity which I preferred to treat as in-patients, whilst the cysts, lipoma and bursæ indicate an enthusiasm for doing odd jobs. Burns and scalds were infrequent; one was very severe and was transferred for skin grafting after the initial shock was treated.

The visiting orthopædic surgeons do out-patient sessions only, but willingly give advice on any cases when one has elected to be responsible for the treatment. Table IV shows the 117 orthopædic cases treated in hospital. Of these 83 were fractures and the lower limb required more admissions owing to the difficulties of navigation. 10 of the cases of fracture of the femur were of the surgical neck. 21 of the orthopædic cases consisted of hammer toes, hallux valgus and exostosis which it gave pleasure to remove or rectify.

Table V shows the gynæcological conditions: 31 of these received their treatment from the visiting gynæcologist. The remainder were a personal responsibility. In 47 cases dilatation and curettage was carried out: in 3 for dysmenorrhœa, the remainder being cases of abnormal bleeding at the menopausal age. This was to ensure that no cancer was missed, and a cervical smear accompanied the uterine scrapings for pathological examination. No latent cancer was discovered in this series. The 24 cases of abortion probably caused the greatest anxiety among the emergencies. Here the giving of blood transfusions was the rule rather than the exception. The 9 cases of salpingography represent my interest in sterility. This measure is not only useful as a diagnostic measure but is also of therapeutic value. Of these 9 patients, 4 became pregnant and 5 healthy children have been produced.

These are the majority of the surgical conditions which have been encountered in one general practice. This paper may not add to medical knowledge but I hope that it does show that the family doctor still practises medicine and even performs some useful surgery.

**Dr. J. Guy Ollerenshaw** (Skipton):

*Medical Emergencies*

A medical emergency may be defined as "A medical situation which calls for the practitioner to take some immediate action at the time it is presented to him."

The recognition of a medical emergency in general practice depends on one or more of three reactions to some deviation from the normal.

These are (1) the reaction of the patient, (2) the reaction of the relatives, and (3) the reaction of the doctor.

The medical emergency which appears at hospital is one in which these reactions have already been sorted out and the case presented to the consultant is one to which the family doctor has reacted as a medical emergency of a particular type.

First let us dispose of the cases which fail to provoke any reaction of alarm in patient, relatives or doctor. For example a baby, apparently well only an hour or two earlier, is found dead in its cot. Post-mortem reveals an acute bronchiolitis which must have been in existence when it was last seen. Such cases, it may be said, belong to the pathologist and the coroner and do not come within our definition; but they are to us a salutary reminder that, far from being a dramatic event, a medical emergency can exist but be so quiet as to pass unnoticed.

At the other extreme is the emergency when the patient, relatives and doctor all recognize it as such: For example: a case of cardiac asthma where a woman rings up and says: "My husband has just come to bed and can't get his breath, he's asked me to send for you. Its awful, please come quickly." Here, patient, relative and doctor all agree that medical attention is required as soon as possible.

In type 1 it is only the patient who is reacting to the event as an emergency. A man rings up and says: "My wife says she is choking and insists that I call you. She doesn't look ill to me but she's all worked up and I'd be glad if you would call." He is not alarmed nor is the doctor who thinks of globus hystericus but it is an emergency to the patient who is demanding immediate action.

Not in all cases in this group does the emergency lie solely in the mind of the patient. Cerebral vascular accidents in known neurotics, for example, sometimes present in this way.

In type 2 the emergency lies in the mind of a relative, as when a simple urticaria almost closes a baby's eyes and a frightened mother calls for an immediate visit from an unperturbed doctor.

More rarely it is only the practitioner who is alarmed as in type 3. For example: A coronary thrombosis. "My husband said I hadn't to trouble you, doctor, but I thought you wouldn't mind telling me what to do. He's got an attack of wind and he doesn't seem able to shift it and he says his left arm aches." Here only the doctor realizes that a medical emergency exists.

To illustrate the three types, very simple examples have been chosen. Usually, of course, the assessment is much more difficult than this and the summons is compounded of two or more types in varying degree. Fortunately all three reactions are usually provoked in the emergencies which are most dangerous to life—poliomyelitis with paralysis, hæmoptyses and hæmatemeses and meningitis (a call to a case of severe headache and vomiting is the red light to most of us). In cerebral vascular catastrophes, epileptic fits, diabetic and insulin comas the patient plays no active part in asking for help but the doctor is usually informed that he is unconscious and this silent reaction does more to bring aid to him quickly than any vocal complaint he could make. The same may be said of the acute mental diseases where a sudden change in his behaviour pattern adds the touch of drama to the incoming call which assures it priority.

The reaction of the relatives is seldom absent but it may be muted when there is an epidemic raging which shows somewhat similar features. Indeed, so may be the reaction of the doctor and I wonder if some infamous poisoners would have been detected if they had waited until an epidemic of gastro-enteritis had been in full swing.

Unless the doctor himself answers the call the amount of anxiety in the mind of the caller is all that can be accurately assessed over the telephone. This is how the majority of emergency calls are first presented, though a trained secretary can ask simple questions which will elicit valuable objective evidence. Crude though it is, much depends on this assessment of the call. Errors of judgment at this early stage can result in dislocation of the doctor's work or, at worst, in delay in visiting an emergency, with consequences which may be grave. A second message coming within two hours of the first is usually an indication for hurry.

Occasionally serious medical emergencies present themselves at a routine surgery consultation and they are particularly important because they usually belong to type 3 where neither the patient nor his relatives have sounded the alarm.

Because the doctor is seeing the patient and not receiving a message from a third person it might be expected that recognition of an emergency would be simpler in these cases but,

in fact, this is often not so. The reasons for this are manifold but the predominating factor is the context in which they are seen—the busy routine surgery and a doctor whose alertness has been dulled by a succession of common-place disorders passing before him. There is a natural tendency, too, to think of one being sent for in an emergency and this sometimes results in a "blind spot" in dealing with patients in the consulting room where the emergency often presents in a quite undramatic way. The missed diagnosis is more often due to the doctor not having thought of that particular condition than to an absence of signs and symptoms which could have led to a correct diagnosis.

For a fuller explanation of the existence of this "blind spot" during surgery hours it is necessary to recognize how different is our approach to our cases from the methods we were taught in hospital. The number of patients to be seen makes impracticable the very complete history and examination which we were taught as students. Instead we tend to take a short history in the light of which several possible diagnoses suggest themselves. If examination with these diagnoses in mind is inconclusive a provisional diagnosis is made and the patient told to come up again. It is easy to condemn this method but most of us see no practicable alternative and the best we can do is to perfect it to the point where we can recognize the case which needs a more formal and systematic approach. It is true that we have always in mind the possibility of serious conditions presenting themselves in unexpected ways; and the chance of missing organic disease in the welter of symptoms produced by our neurotic patients is a constant fear; but we do at least have these possibilities in mind. The medical emergency, on the other hand, is a disorderly event which we do not associate with the general pattern of our surgeries and so it does not enter into the first differential diagnosis. A patient once died of his coronary thrombosis in my examination room. This event shocked me more because I was mentally unprepared for this sort of event in the course of a surgery than because of its tragic outcome. In this case the diagnosis was obvious and no treatment could be effective. Very different, however, was the case of a known psychoneurotic patient who passed through the consulting room as he had done many times before and straightway threw himself into the canal. The possibility of this being a medical emergency had not arisen during the consultation, but in the light of subsequent events it was thought that there were some clues in his demeanour and complaints which might conceivably have led to a correct assessment of emergency. Less dramatic but in my view a true emergency is the situation when a "neurotic" patient lets fall a remark which reveals or hints at the problem underlying his symptoms.

In the absence of his own doctor a man asked a partner for a repeat prescription of his stomach powder which he had been taking for his duodenal ulcer for several years. While writing the prescription the partner asked him if he had any idea what had brought on the pain on this occasion, specifically mentioning nervous stresses. These the man denied but as the doctor handed him the prescription he said "Well there's another thing I'd like to ask you about"; he then disclosed that sexual relations with his wife had been unsatisfactory throughout the nine years of married life.

The tranquillizer and an appointment to "come and see me to-morrow when I can spend more time with you" will not do in such a case; sufficient time has to be given to the case there and then to convince the patient that his trouble is at least understood and that hope of relief exists. Unless this has been done, to-morrow he may have regretted his impulse to confide and the doctor has lost his access to the problem.

The reaction of relatives serves a useful purpose in bringing help to the sufferer, but not infrequently it is in the nature of a second episode in a sort of chain reaction in which patient, relatives and doctor are all involved. The patient, seeing the concern of the relatives, often has the symptoms of anxiety or fear added to his original complaint—tachycardia, respiratory disturbance, sweating, and tense muscles simulating abdominal rigidity. Impressed by the resulting picture the general practitioner may remove the patient to hospital where these added symptoms disappear and the condition as presented in the ward is very different from that seen in the bedroom. However courteous the consultant's letter, when the patient is discharged next day, the practitioner feels slightly embarrassed if not positively humiliated. This illustrates the difference between medical emergencies in hospital and general practice. At the general practitioner level an emergency was present but the doctor had incorrectly evaluated the factors comprising it.

Any doctor who is satisfied to stop at treating the physical or mental condition which he has found in the patient is taking a far too narrow view of his functions and in a general practitioner to ignore the totality of the emergency is unpardonable. This I am sure was well understood by all general practitioners in the days when medicine was an art and science its very humble handmaid instead of the austere and slightly intimidating partner which it

is to-day. A rather fussy woman sent in the night on behalf of her husband, who was in pain. The doctor gave the immediate treatment and arranged for hospital admission next day. He then left the house rather abruptly. Later the wife complained bitterly to a partner. He was able to convince her that the doctor's treatment of her husband was correct but her sense of grievance remained. It was obvious that she was really complaining of the treatment meted out to her—or rather the lack of treatment. Her tension would have been relieved by a few words of explanation and reassurance about her husband but in his preoccupation with the patient the doctor had failed to do this.

The state of this woman's mind was part of the total emergency which existed and which it is our duty to recognize and treat.

This larger emergency is the reaction of other members of the family to an event which has suddenly shattered the pattern of home life. The father, instead of setting off to provide for the family, lies delirious upstairs, or the mother, instead of bustling round the house, lies moaning on the settee, or the child lies pale and unresponsive in its cot. The immediate reaction by the rest of the family is fear: for home has always been regarded as a secure haven in a rather frightening world. Even if it is not a very happy home it is to its members at the centre of things and its sudden disorganization leaves them lost and afraid. Because we know the cause of the disturbance—the patient's condition—and have some idea of what is likely to happen, we are in a better position than anyone else to start the process of adjustment to the new situation. Often, happily, we can give immediate reassurance that soon things will return to normal and that in the meantime such and such steps must be taken. But even when things are at their grimmest we can, from our experience, indicate how the situation can be dealt with. Once the mind is turned from helpless fear to constructive thinking the crisis is on its way to resolution.

The truth we seek is sometimes missed not because it is hidden at the bottom of a well but because, though out in the open, it stands alongside other truths which are so obvious that they get only a cursory glance. It is for this reason that this paper has directed attention to the following obvious truths:

(1) Emergencies can happen at any time in any place and to any person.

(2) In general practice a medical emergency presents not as a single problem, but as a complex, in which the part played by relatives may help to clarify or to obscure the central event.

(3) Serious organic disease is not a necessary component of a medical emergency in general practice.

(4) Treatment has to be directed not to the patient alone, but to the total situation which surrounds him.

## DISCUSSION ON INFLUENZA

**Major R. J. C. Hart, R.A.M.C. (London):**

*Virology*

The virus laboratory at the Royal Army Medical College was investigating outbreaks of influenza throughout 1957. The sources of positive findings during the year are shown in Fig. 1.

During the early part of the year there were a number of outbreaks due to the Dutch '56 strain of influenza virus A and one outbreak due to virus B. The Asian strain of virus A was first isolated in April from material sent to the College from cases in Hong Kong. While the virus was spreading through the Far East in the late spring and early summer, a number of outbreaks occurred on homeward bound troopships, and some of these landed cases in England. Apart from these, the first cases in the Army in the United Kingdom did not develop until early August when a number of units in Western Command suffered outbreaks. Further outbreaks occurred in rapid succession in other Home Commands and Germany, and somewhat irregularly in Middle East Command, Malta and Gibraltar.

Surgeon-Major Bulow will be describing his experiences with a large unit outbreak of influenza due to the Asian strain of virus A, Colonel Johnstone will discuss the complications, and Colonel Pace will deal with the epidemiology of the disease in Western Command.

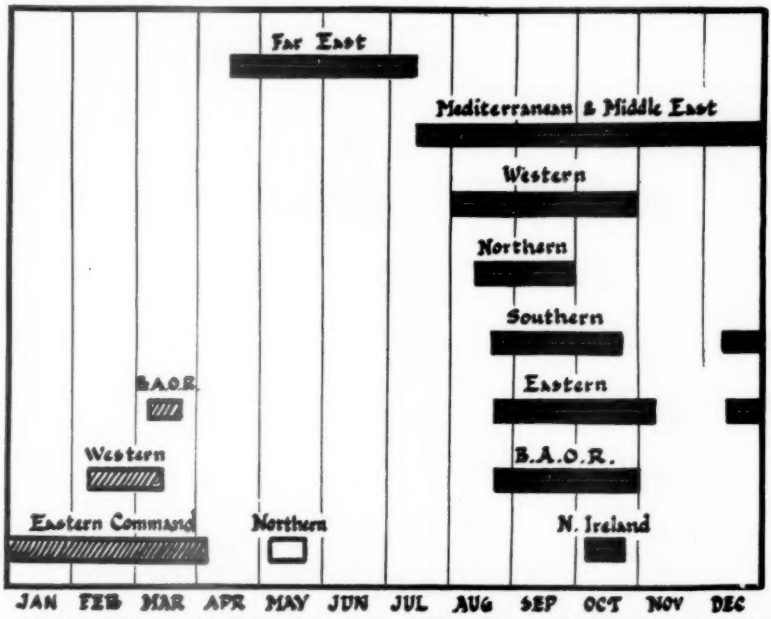

FIG. 1.—Incidence of influenza in the Army—1957. (From specimens examined in the Virus Laboratory, R.A.M. College.) Black=virus A (Asian), white=virus A (Dutch '56), hatched=virus B.
